## Section 1: Introduction

The Public Utility District No. 1 of Douglas County (Douglas PUD) funds hatchery programs to compensate for inundation of spawning habitat (Wells Hatchery steelhead and summer Chinook Salmon inundation programs) and lost harvest opportunities related to the construction of the Wells Hydroelectric Project and for mortality associated with operation and passage at the Project (Methow Hatchery spring Chinook Salmon and Wells Hatchery steelhead No Net Impact [NNI] programs) as part of the Anadromous Fish Agreement and Habitat Conservation Plan (HCP) for the Wells Hydroelectric Project (Wells HCP 2002). Douglas PUD also operates programs on behalf of, in collaboration with, and funded by, Grant County PUD (Methow Hatchery Spring Chinook Salmon and Wells Hatchery steelhead) to meet mitigation obligations specified in Grant PUD's Priest Rapids Salmon and Steelhead Settlement Agreement (SSSA) and associated Biological Opinion for the Priest Rapids Project. Douglas PUD also operates on behalf of, and funded by, Chelan County PUD to meet mitigation obligations associated with operation and passage at Rocky Reach Hydroelectric Project (Methow Hatchery Spring Chinook salmon NNI program) as part of the Anadromous Fish Agreement and HCP for the Rocky Reach Hydroelectric Project (Rocky Reach HCP 2002). The Hatchery Committees developed specific goals for these hatchery programs, which are described in Monitoring and Evaluation Plans (M\&E Plan) for PUD Hatchery Programs (Wells HCP HC 2005; Hillman et al. 2013). More specifically, these programs are intended to:

1. Support the recovery of ESA-listed species by increasing the abundance of the natural adult population, while ensuring appropriate spatial distribution, genetic stock integrity, and adult spawner productivity (Methow spring Chinook Salmon, Methow summer steelhead, Okanogan summer steelhead).
2. Increase the abundance of the natural adult population of unlisted HCP plan species, while ensuring appropriate spatial distribution, genetic stock integrity, and adult spawner productivity. In addition, provide harvest opportunities in years when spawning escapement is sufficient to support harvest (Methow summer/fall Chinook Salmon).
3. Provide salmon for harvest and increase harvest opportunities, while segregating returning adults from natural tributary spawning populations (Wells summer/fall Chinook Salmon).

These programs occur at either Wells Hatchery, located on the west bank of the Columbia River adjacent to Wells Dam (Columbia River km 830), or Methow Hatchery, located on the Methow River (Methow River km 83) upstream of the town of Winthrop, Washington. Hatchery programs at these facilities have been categorized within the M\&E Plan under three categories; conservation, safety-net, or harvest-augmentation programs. Conservation programs (Methow Composite [Methow and Chewuch], and Twisp river spring Chinook Salmon; Twisp and

Okanogan River steelhead) are integrated hatchery programs intended to increase natural production of targeted fish populations. A fundamental assumption of this strategy is that hatchery programs will increase the number of fish returning to the spawning grounds, which will therefore increase the number of wild fish produced assuming that hatchery fish are reproductively similar to naturally produced fish. Safety-net programs (Methow and Columbia River steelhead) are an extension of conservation programs, intended to provide a demographic and genetic reserve of hatchery adults in years of low returns. In years of high adult abundance, safety-net programs would function like harvest-augmentation programs (e.g., Wells summer Chinook Salmon); increasing harvest opportunities while limiting interactions with natural origin conspecifics. Harvest-augmentation programs are intended to provide opportunities for harvest while having minimal interaction with natural populations.

The M\&E Plan adopted by the Wells HCP Hatchery Committee (Hillman et al. 2013) consists of 12 objectives designed to monitor whether the intended management objectives of conservation, safety-net, and harvest augmentation hatchery programs are being met. These objectives are:

Objective 1: Determine if conservation programs have increased the number of naturally spawning and naturally produced adults of the target population and if the program has reduced the natural replacement rate (NRR) of the supplemented population.

Objective 2: Determine if the proportion of hatchery fish on the spawning grounds affects the freshwater productivity of supplemented stocks.

Objective 3: Determine if the hatchery adult-to-adult survival (i.e., hatchery replacement rate, HHR) is greater than the natural adult-to-adult survival (i.e., natural replacement rate, NRR ) and the target hatchery survival rate.

Objective 4: Determine if the proportion of hatchery-origin spawners ( pHOS or PNI ) is meeting the management target.

Objective 5: Determine if the run timing, spawn timing, and spawning distribution of the hatchery component is similar to the natural component of the target population or is meeting program-specific objectives.

Objective 6: Determine if the stray rate of hatchery fish is below the acceptable levels to maintain genetic variation among stocks.

Objective 7: Determine if genetic diversity, population structure, and effective population size have changed in natural spawning populations as a result of the hatchery program.

Objective 8: Determine if hatchery programs have caused changes in phenotypic characteristics of natural populations.

Objective 9: Determine if hatchery fish were released at the programmed size and number.

Objective 10: Determine if appropriate harvest rates have been applied to conservation, safetynet, and segregated harvest augmentation programs to meet the HCP/SSSA goal of providing harvest opportunities while also contributing to population management and minimizing risk to natural populations.

Objective 11: Determine if the incidence of disease has increased in the natural and hatchery populations.

Objective 12: Determine if the release of hatchery fish affects non-target taxa of concern (NTTOC) within acceptable limits.

Each objective has a suite of associated statistical hypotheses tested by analyzing variables derived or measured from the target populations through the implementation of annual work plans approved by the Wells HCP Hatchery Committee. Most of these analyses will be conducted at 5-year intervals specified within the M\&E Plan (Hillman et al. 2013). This report is the eleventh annual report, summarizing data collected during 2016 required to address the program-specific objectives of the M\&E Plan and is consistent with the implementation plan approved by the Wells HCP Hatchery Committee (MRT 2015). Data collection in 2016 was conducted by Washington State Department of Fish and Wildlife (WDFW) personnel through a contract between WDFW and Douglas PUD with the exception of those spring Chinook (sections M6-M8, WN1) and steelhead (WN1) spawning ground surveys conducted by U.S. Fish and Wildlife Service personnel.

## Section 2: Summary of Methods

Data collection and fish sampling conducted in 2016 followed the general methods described within the M\&E Plans (Wells HCP HC 2005; Hillman et al. 2013) or within recent annual reports (e.g., Snow et al., 2012). In some instances, methods and protocols are developed and approved annually through the Wells HCP Hatchery Committee (i.e., broodstock collection protocols) and are included as appendices within this report. In the following section we briefly summarize the methods used for completing specific tasks or objectives within the M\&E Plan.

## 2.1: Broodstock Collection and Sampling

Broodstock collection methods, locations, and numeric targets for 2016 were described in full in annual broodstock collection protocols (Tonseth 2016). Spring Chinook Salmon and steelhead collection at Wells Hatchery attempted to collect broodstock in a manner representing the run-at-
large of the target species passing Wells Dam. Collection of broodstock at the Twisp River weir (steelhead), and the Methow (spring Chinook Salmon and steelhead) and Wells (summer Chinook Salmon and summer steelhead) hatchery outlet channels is conducted such that extraction of natural origin fish does not exceed $33 \%$ of natural origin returns. Biological sampling of adult fish was conducted during broodstock collection and spawning activities to estimate the migration timing, age-structure, sex ratio, and the estimated total return and extraction rate of hatchery and naturally produced spring Chinook Salmon and steelhead passing Wells Dam. Samples collected include fork and post-eye to hypural plate ( POH ) lengths (mm), sex, scales, origin, hatchery marks, fecundity, and enzyme-linked immunosorbent assay (ELISA) sampling to assess the relative incidence of bacterial kidney disease in spawned spring Chinook Salmon females. This sampling provided the information necessary to assess age-at-maturity, length-at-maturity, and fecundity-at-age. In addition, all fish were scanned for passive integrated transponder (PIT) tags and coded-wire tags (CWT’s). Recorded PIT codes were uploaded to the PTAGIS database (www.ptagis.org), and CWT’s were recovered from all lethally spawned fish and reported to the Regional Mark Processing Center website whose collective databases serve as the primary repository for CWT data; known as the Regional Mark Information System (RMIS).

Digital video records of fish passage at Wells Dam between 22 May and 2 July for both fish ladders were reviewed to exclude summer Chinook Salmon from the spring Chinook Salmon count and vice versa, based on physical characteristics of the fish. In general, we reviewed the three busiest hours of passage per ladder per day during this time, and expanded the proportion of spring and summer Chinook Salmon during those hours to estimate total passage of each species for the day. The number of fish that were double counted (i.e., re-ascensions) or fell back (i.e., fell below the dam without re-ascending) were estimated based on PIT-tag detections at in-stream interrogation sites and mainstem Columbia and Snake River dams. Proportions of fish detected at locations downstream of Wells Dam and records of fish migrating through Wells Dam multiple times were expanded to remove fall-backs and multiple-counts from the run-atlarge estimate at Wells Dam. No estimates of predation, pre-spawn mortality, or illegal removal (i.e., poaching) were made.

## 2.2: Within-hatchery Monitoring

After spawning, progeny were monitored from incubation to release to assess life-stage specific survival rates. The survival of juveniles in the hatchery is a monitoring indicator (an indicator meant to inform or augment primary indicators) in the M\&E Plan used in cases when release goals were not met. This indicator is useful for explaining why the number of fish released did not meet goals despite adequate broodstock collection. The number of juvenile fish released was calculated based on a census of the population during fish tagging or marking, minus mortality that occurred between marking and release. However, the number of steelhead released from

Wells Hatchery was calculated as the sum of all fish trucked to a release location. The number of fish within each truckload was determined by applying the mean number of fish per pound (FPP) at truck-loading by the weight of fish loaded as estimated through examination of a gravimetric tube attached to each truck. A sample of 200 fish were collected just prior to release from each stock to estimate pre-release mean fork length, weight, FPP, condition factor (K), and coefficient of variation (CV) of length. Pre-release sampling results were compared to target release values described in Murdoch et al. (2012; Table 2.1). Observed survival rates, size-atrelease, and number at release were compared with life-stage specific target survival rates within the M\&E plan (Table 2.2).

Table 2.1. Draft Target release values for Wells and Methow hatchery program steelhead and salmon in 2016 (pending finalization in M\&E Plan by the HCP HCs).

| Release location, species | Release number | Fork length |  | Weight |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Mean (mm) | CV | Mean (g) | FPP |
| Twisp River steelhead | 48,000 | 191 | <10 | 75.6 | 6 |
| Methow River steelhead | 100,000 | 191 | <10 | 75.6 | 6 |
| Okanogan River steelhead | 90,000 | 191 | $<10$ | 75.6 | 6 |
| Columbia River steelhead | 160,000 | 191 | <10 | 75.6 | 6 |
| Wells age-1 summer Chinook | 320,000 | 168 | $<7$ | 45.4 | 10 |
| Wells age-0 summer Chinook | 484,000 | NA | $<7$ | 9.1 | 50 |
| Methow River spring Chinook | 133,249 | 137 | $<10$ | 30.2 | 15 |
| Twisp River spring Chinook | 30,000 | 135 | <10 | 30.2 | 15 |
| Chewuch River spring Chinook | 60,516 | 136 | <10 | 30.3 | 15 |

Table 2.2. Life-stage survival rate standards for spring Chinook, summer Chinook, and steelhead reared at the Wells and Methow hatcheries.

| Life stage | Survival standard (\%) |
| :--- | :---: |
| Collection-to-spawning-female | 90 |
| Collection-to-spawning-male | 85 |
| Unfertilized egg-to-eyed | 92 |
| Eyed egg-to-ponding | 98 |
| 30 d after ponding | 97 |
| 100 d after ponding | 93 |
| Ponding-to-release | 90 |
| Transport-to-release | 95 |
| Unfertilized egg-to-release | 81 |

All fish at the Wells and Methow hatcheries receive either an internal tag (CWT), external mark (e.g., adipose fin-clip), or a combination of both (e.g., fin-clip and CWT) prior to release. In addition, representative groups of fish from some populations received a PIT tag prior to release to estimate migration timing, emigration survival, and smolt-to-adult survival (SAR). Mark retention was estimated prior to release by collecting a random sample of fish and scanning for marks and tags visually (ad-clipped fish) or with electronic detection equipment (CWT'd fish). Hatchery mark retention and release information is provided to the RMIS database annually so that subsequent recaptures of marked fish can be expanded to account for un-marked fish.

## 2.3: Natural Origin Juvenile Productivity

Sampling of juvenile fish was conducted using rotary smolt traps in the Twisp and Methow rivers, and through hook-and-line angling and electrofishing in the Twisp subbasin. Smolt trapping was conducted to estimate the number of emigrating salmonids from the Twisp River (Twisp River trap at rkm 2) or the Methow River basin (Methow River trap at rkm 30). Trapping occurred between late-February and early December at both trap sites. A detailed description of smolt trapping methods can be found in Snow et al. (2012) and in Attachment A. In general, all species captured at each trap site were identified and enumerated by origin (hatchery or natural) on a daily basis. Biological data collected from salmonid species included fork length (mm), weight (g), hatchery mark, PIT tag code (if present), state of smoltification (steelhead), and scale samples were collected from natural-origin steelhead, Bull Trout, and Cutthroat Trout. To estimate capture efficiency for each smolt trap and trapping position, some captured fish were marked (PIT tag and/or fin-clip) and released upstream of each trap site to determine recapture rates. These mark/recapture trials were conducted over a wide range of discharges so that a linear regression model relating discharge and capture efficiency could be developed for each separate trapping position at each site.

Total emigration estimates for steelhead, spring and summer Chinook Salmon, and Coho Salmon were calculated as the sum of the daily capture of each species at each site, expanded by the sitespecific capture efficiency estimated through the application of the discharge/trap efficiency linear regression model. Because these species may emigrate from their natal tributaries over multiple years, emigration estimates of different ages of fish from the same brood were summed to estimate total emigration for specific broods of fish.

Juvenile spring Chinook Salmon and steelhead were captured by hook-and-line angling or through backpack electroshocking in the Twisp subbasin to estimate over-winter (parr to smolt) and smolt to adult survival and to estimate stray rates of natural-origin adult spawners. Captured fish were held briefly in 19L buckets, then anesthetized in a solution of MS-222 prior to biosampling. Fork length ( mm ) and weight (g) were measured for each fish and those with a fork length greater than 54 mm were PIT tagged prior to release. In general, scale samples were
collected from all steelhead with a fork length greater than 89 mm . Each release site was georeferenced with a hand-held global positioning system (GPS) unit so that approximate river kilometer for each release site could be determined and included within the tagging file uploaded to the PIT tag information system (PTAGIS) website. Parr to smolt survival was calculated from PIT tag detections using the Cormack-Jolly-Seber (CJS) survival estimates obtained from the Data Access Real Time website (DART) maintained by the University of Washington’s School of Aquatic and Fishery Sciences. Smolt to adult and stray rate information was calculated from adult PIT tag detections at mainstem Columbia River dams and in-stream PIT tag detection arrays. Additionally, PIT tagged juvenile Chinook were used to estimate Chinook emigration from the Twisp River during periods when the smolt trap was not operating (e.g., winter) by expanding PIT tag detections at the Twisp River PIT tag array by the expected array efficiency as determined by mark/recapture sampling and the expected PIT tag rate determined from smolt trap sampling.

## 2.4: Spawning Ground Surveys

Spawning ground surveys were used to evaluate spawn timing and spatial distribution of spring Chinook Salmon and steelhead. The Methow River basin was divided into four geographic subbasins: upper Methow River (upstream of Winthrop), lower Methow River (downstream of Winthrop), Chewuch River, and Twisp River. Each subbasin was further divided into survey sections based on stream length and unique natural or anthropogenic features (Tables 2.3-2.6). Spring Chinook Salmon redd surveys were conducted weekly between about 1 August and 30 September throughout their spawning area in the Methow Basin. Steelhead surveys occurred weekly between about 15 March and 31 May throughout the Twisp River subbasin, and were considered total redd counts. Steelhead surveys in the lower Methow subbasin were conducted during the same period, but primarily within selected index areas. River sections outside the selected index areas were surveyed once when spawning was near completion. The application of the surveyor efficiency model previously developed was not applied to redd counts in 2016 therefore redd totals in lower Methow River reaches should be considered minimum values (Attachment D). In general, each redd was individually marked with biodegradable flagging tape and the survey date, redd number, and general stream channel location were recorded on each flag. Steelhead escapement estimates in the Chewuch and upper Methow subbasins, and in the lower Methow River tributaries were produced by expanding PIT tag detections at in-stream PIT tag arrays (Attachment D).

Carcasses recovered during spring Chinook Salmon spawning ground surveys were sampled to determine origin, sex, fork length, POH length, egg retention (females), and scale samples were collected from each carcass when possible. Carcasses were scanned for PIT tags using handheld devices and detected tags were recorded. A GPS location was collected where each carcass was discovered. Tissue samples were collected from hatchery- and natural-origin fish for genetic analyses. All carcasses were scanned for CWTs using hand-held electronic detection wands (because many spring Chinook Salmon released from Methow Basin hatcheries in recent years have been tagged with a CWT but have not been externally marked, thus requiring the use of electronic detectors) and when present the tag was collected for analysis. Coded-wire tag data are uploaded to- and retrieved from the RMIS database to calculate harvest rates, adult survival, age-at-return, and straying of CWT'd hatchery fish. Coded-wire tag data availability in the RMIS database is often two or more years behind the collection event, thus monitoring indicators that rely on these data must be continually updated (Table 2.7).

The hatchery replacement rate (HRR) and natural replacement rate (NRR) are two primary indicators that rely on CWT data. For each brood of CWT'd hatchery fish released, the sum of estimated CWT returns available in the RMIS database is divided by the number of adult broodstock used to produce the brood releases to calculate HRR. For NRR, the number of adult returns is estimated as described in the Harvest Monitoring section 2.5 below, then divided by the estimated naturally spawning (hatchery and wild fish) population for the cohort. Data collected from redd and carcass surveys, stock assessment at Wells Dam, and CWT data retrieved from the RMIS database are used to assess spawn timing and distribution, SAR, HRR, NRR, harvest exploitation rates, straying, length- and age-at-maturity, and the proportion of hatchery origin spawners (pHOS) and the proportionate natural influence (PNI) within the spawning subbasins. Because too few carcasses are recovered during steelhead surveys to estimate spawn timing, distribution, and straying of specific hatchery stocks, evaluation of these indicators occurs at specific locations where adult steelhead are sampled (e.g., Twisp weir) or through analysis of PIT tag data collected at multiple in-stream antenna arrays throughout the Methow Basin. Adult steelhead PIT tag detections at each spawning tributary antenna/array were evaluated to assess the date of tributary entry and tributary residence during the spawning period. Fish that entered tributaries on a date consistent with a spawning migration (March-May) and were not subsequently detected anywhere in the Methow Basin downstream of the specific antenna/array, were considered to have spawned above that antenna/array. Hatchery fish that met these criteria within a tributary other than their tributary of release were considered strays.

Table 2.7. Broodstock requirements and smolt release, smolt-to-adult survival (SAR), and hatchery replacement rate (HRR) goals for PUD hatchery program steelhead and Chinook Salmon. SAR, adult equivalent, and smolt per adult values were derived from the HRR target and smolt release goals.

| Program | Broodstock | Smolts <br> released | SAR | Adult <br> equivalents | \# Smolts/ <br> adult | HRR |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Wells age-1 summer Chinook | 178 | 320,000 | 0.003 | 943 | 339 | 5.3 |
| Wells age-0 summer Chinook | 284 | 484,000 | 0.001 | 625 | 774 | 2.2 |

| Methow Comp. spring Chinook | 104 | 193,765 | 0.002 | 468 | 414 | 4.5 |
| DCPUD safety-net steelhead | 170 | 260,000 | 0.01 | 3,332 | 78 | 19.6 |
| Twisp WxW steelhead | 28 | 48,000 | 0.01 | 549 | 87 | 19.6 |
| GCPUD-Okanogan steelhead | 42 | 80,000 | 0.01 | 823 | 97 | 19.6 |

The M\&E Plan evaluates straying of hatchery fish by assessing the overall stray rate of each release group (donor population) and by evaluating the proportion of stray hatchery fish within the spawning escapement of other (recipient) populations within each spawning year (Hillman et al., 2013). To further evaluate stray rates, adult returns of hatchery origin fish were categorized depending on their release and recovery location (Table 2.8).

Table 2.8. Categories and definitions used to evaluate homing and straying of hatchery fish.

| Category | Definition |
| :--- | :--- |
| Donor population | Hatchery population being evaluated; grouped by species, brood, and <br> release location. |
| Recipient population | Spawning population of species being evaluated; may be at the <br> tributary (e.g., Methow, Twisp, Chewuch), or basin scale (e.g., Entiat, <br>  <br> Wenatchee). |
| In-basin homing | Fish homed to its release stream (population). |
| In-basin stray | Fish strayed to another population within its release basin. |
| Out-of-basin stray | Fish strayed to a population in a different release basin. |

Fish retained for broodstock at Wells Dam or those for which the CWT code could not be used to identify release subbasin (e.g., 1998 and 2000 Methow and Chewuch spring Chinook Salmon releases) were excluded from stray rates calculations.

## 2.5: Harvest Monitoring

The harvest of fish stocks covered under the M\&E Plan is monitored through the use of the RMIS database (spring and summer Chinook Salmon), or through local creel sampling efforts (steelhead). Depending on fishery type, harvest of natural origin fish can be intentional (i.e., non-selective fishery) or unintentional (e.g., post-release mortality in selective fisheries).
Because non-selective fisheries may retain spring Chinook Salmon regardless of mark type, the exploitation rate of specific hatchery stocks (e.g., Methow River) should be the same as for naturally produced fish from the same population. Harvest of natural origin fish, and hatchery fish that were not adipose-fin clipped (i.e., Methow Hatchery spring Chinook Salmon), was estimated using the exploitation rates of surrogate hatchery stocks where the run-timing and exposure to fisheries was assumed to be similar to that of natural origin fish.

Coded-wire tag data queried from the RMIS database was expanded by the sample rate of the data collection event, and the tag-code specific mark rate for the population estimated during inhatchery monitoring. The expanded data was sorted by fishery code and site name, and grouped into four categories to evaluate M\&E Plan indicators including HRR, NRR, SAR, and straying:

1. Broodstock
2. Spawning ground
3. Ocean fishery
4. Freshwater fishery

Within the broodstock and spawning ground categories, subcategories were employed to designate target areas (i.e., stream or hatchery of release), and non-target areas (i.e., stray locations). Within the ocean and freshwater categories, subcategories were developed to designate commercial, sport, or tribal harvests. Wells summer Chinook Salmon are propagated for harvest augmentation and all spawning ground recoveries of these fish were considered to be in non-target areas.

Since ESA listing in 1997, steelhead returns have had to meet specific requirements for abundance and genetic composition before a local fishery could be considered. Because hatchery steelhead were not coded-wire tagged, no stock-specific fishery harvest estimate could be generated from the RMIS database. Instead, creel census was used to estimate harvest and indirect mortality (i.e., hooking mortality) associated with local fisheries. Creel census was conducted consistent with roving creel census methodologies described by Malvestuto et al. (1978). An estimated hooking mortality rate of $5 \%$ was used to estimate mortality of wild and hatchery fish released by sport anglers (WDFW 2016). Angler interviews produced a catch-per-unit-effort (CPU) statistic where one unit of effort was equal to one angler fishing for one hour. The total number of steelhead captured was determined by multiplying the total angler effort by the overall CPU for each fishery location.

## Section 3: Methow Hatchery Spring Chinook

This section focuses on the Methow Hatchery spring Chinook program which includes broodstock collected at Wells Dam, the Twisp River weir, and the Methow and Winthrop hatcheries. These collections produced juvenile Twisp and Methow Composite stock spring Chinook released into the Twisp, Methow, and Chewuch subbasins.

## 3.1: Broodstock Collection and Sampling

Trapping of the 2016 brood Methow Hatchery spring Chinook occurred concurrently with run-at-large evaluation at Wells Dam between 2 May and 23 June, 2016. During this time, a total of 61 wild origin fish were retained for broodstock, representing $9.3 \%$ of the estimated wild fish escapement above Wells Dam during the trapping period ( $N=659$ ). Trapping and collection of hatchery origin spring Chinook was also conducted at the Methow Hatchery outfall trap. Most fish trapped at that location were transferred to Winthrop National Fish Hatchery for broodstock or surplus purposes, but some hatchery fish were retained for broodstock or were euthanized to reduce pHOS (Table 3.1). Spring Chinook trapping occurred at the Twisp River weir between 27 May and 18 July, 2016. During this time, a total of 11 wild and 4 hatchery origin fish were retained for broodstock (Table 3.1), and 15 additional hatchery origin age-3 males (i.e., jacks) were euthanized to reduce pHOS at the Twisp weir. Historically, most spring Chinook collected have been used for spawning (Table 3.1). Fish collected for broodstock but not utilized (e.g., excess males, non-viable females) were considered surplus.

Table 3.1. Collection of spring Chinook and the prespawn mortality (PSM), surplus mortality (Mort), and spawning (Spawn) by fish origin (hatchery or wild). Fish for which the origin or disposition (PSM, Spawn, etc.) are unknown (U) are included in the hatchery total for each brood.

| Brood year | Wild Chinook |  |  |  |  | Hatchery Chinook |  |  |  |  | Total |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Length and Age at Maturity

Most spring Chinook spawned at Methow Hatchery are age-4 hatchery origin fish. Because of this, sample sizes within ages and sexes are generally too small to make valid comparisons within years (Table 3.2). These analyses will be conducted across years in Statistical Reports scheduled at 5-year intervals (e.g., Murdoch et al. 2012).

Table 3.2. Mean fork length (cm) by brood, origin, sex, and age at return of spring Chinook retained for broodstock at Methow Hatchery.

## Sex Ratio and Fecundity

The overall mean sex ratio of the Methow Composite and Twisp stock fish retained for broodstock (excludes released fish) favored females (Table 3.3). For the 2014 brood, the sex ratio favored female fish in the Methow Composite program, and male fish in the Twisp program. Of the female fish retained, fecundity of the 2014 brood was generally higher for hatchery origin fish than for natural origin fish within each program, but sample sizes for hatchery females was very low. Overall fecundities of the 2014 brood were above the value used in broodstock protocol calculations for hatchery fish $(3,556)$ but below the value used for wild
$(3,751)$ Methow Composite females. Similarly, fecundity of Twisp hatchery origin females was above the value used in broodstock protocol $(3,504)$, but below the value used for wild origin females $(3,699)$.

Table 3.3. Sex ratio (Male/Female) and mean fecundity by return year and origin of spring Chinook retained for broodstock at Methow Hatchery.

## ELISA Monitoring

Adult female Chinook spawned at Methow Hatchery are screened for the presence of Bacterial Kidney Disease (BKD) using an ELISA assay. Results of this test are grouped into four general categories based on the optical density (OD) of each sample. Overall, at least 72\% of OD values from sampled Methow Composite and Twisp program females have been in the "Below-low" category. For most broods of Twisp and Methow Composite stock fish, management actions specified in broodstock collection protocols (Tonseth 2014) have increased the proportion of progeny with lower ELISA OD values retained at Methow Hatchery. For the 2014 brood, all Twisp females were in the below-low category, and all Methow Composite females were in the below-low category except for the single hatchery female spawned (Table 3.4).

Table 3.4. Enzyme-linked immunosorbent assay (ELISA) test results (\% of sampled fish) by return year and ELISA category for female spring Chinook spawned at Methow Hatchery. Values are listed for all fish spawned (before), and for all fish retained for yearling-release (after) following ELISA management (i.e., culling), removal of non-viable fish, and release of unfed fry.

## 3.2: Within-hatchery Monitoring

## Juvenile Marking and Tagging

Juvenile Spring Chinook at Methow Hatchery are tagged with a CWT prior to release and broods prior to 2000 were also marked with an adipose fin-clip. The Methow Composite and Twisp programs have been marked with only a CWT for the 2000-2014 brood releases (Tables 3.53.6). Spring Chinook are acclimated on-station at Methow Hatchery (Methow-release Methow Composite stock) or transferred to the Twisp or Chewuch acclimation ponds prior to release
(Twisp releases of Twisp origin and Chewuch-release Methow Composite stocks). Additionally, in some years, fish have been released from Biddle’s Pond (Wolf Creek; broods 2002, 2008, and 2009) and/or Mid-Valley Pond (Methow River; broods 2010, 2011, and 2012). Acclimation time averaged 28 days for the Chewuch River releases and 164 days for Methow Hatchery releases (Table 3.5). Twisp River releases have been acclimated for 28 days on average prior to release (Table 3.6).

For the 2014 brood, Twisp River releases achieved $121 \%$ of the release goal of 30,000 smolts specified in broodstock collection protocols (Tonseth 2014; Table 3.6). Releases into the Methow River achieved $118 \%$ of the release goal of 133,249 smolts specified for Methow Composite stock release in the broodstock collection protocols (Table 3.5). Brood year 2014 Chewuch River releases were conducted under a separate program operated by Chelan County PUD and achieved $119 \%$ of the release goal of 60,516 smolts specified in broodstock collection protocols.

Table 3.5. Pre-release tagging of spring Chinook by brood year released into the Methow and Chewuch rivers.

## Juvenile Size and Condition at Release

Size-at-release fork length and weight targets for DCPUD program fish are described in Murdoch et al. (2012). Releases into the Methow, Twisp, and Chewuch rivers attained 95\%, $97 \%$, and $98 \%$ respectively, of the target fork lengths prior to release (Table 3.7). Coefficient of variation (CV) in length for 2014 brood releases was slightly above the target value of nine for Twisp releases (9.9), but below nine for Methow (8.8) and Chewuch (7.5) releases.

Table 3.7. Pre-release mean fork length (mm), weight (g), coefficient of variation (CV), standard deviation (SD), and condition factor (K) of Methow Hatchery spring Chinook.

| Brood | Fork length (mm) |  |  | Weight (g) |  |  |  | K |

## Survival Estimates

In-hatchery survival of Methow Composite and Twisp program fish from the 2014 brood exceeded target values (Wells HCP HC 2005; Table 3.8). Overall (all-year average) mean survival in most categories was also above target values (Table 3.8).

Table 3.8. Survival (\%) of Methow Hatchery spring Chinook by brood and survival category.

| Brood | $\begin{array}{r} \text { Collect } \\ \text { spaw } \end{array}$ | $\begin{aligned} & \text { on to } \\ & \text { ling } \end{aligned}$ | Unfertilized egg-eyed | Eyed eggponding | 30 d after ponding | 100 d after ponding | Ponding to release | Transport to release | Unfertilized egg-release |

### 3.3 Natural Origin Juvenile Productivity

Smolt trapping was conducted in 2016 in the Methow and Twisp Rivers to estimate the productivity (smolts per redd) of spring Chinook spawning in the Methow and Twisp river basins. Because juvenile Chinook emigrate as age-0 fall parr and as age- 1 spring smolts, productivity estimates are the result of combining trapping effort from two years to complete estimates for each brood. Spring Chinook fry that emigrate during the spring past the Twisp and Methow smolt traps are not included in spring Chinook production estimates at those sites, thus their contribution to overall juvenile production is unknown (Attachment A).

## Emigrant and Smolt Estimates

## Methow Trap

Trapping at the Methow River trap site (rkm 30) occurred between 19 February and 5 December 2016 using smolt traps with a 1.5 m or 2.4 m cone diameter. These traps were operated in two
different trapping positions depending on the river discharge at the site. Trapping at the Methow site was interrupted on two occasions for a total of three days because of high flow and debris. Spring Chinook production estimates were based on daily capture of wild Chinook emigrants, expanded by the estimated trap efficiency derived from a trap efficiency/flow model developed for each trap configuration (Attachment A). Juvenile Chinook captured during the spring of each year as yearling emigrants were assumed to be spring Chinook. Juvenile Chinook captured in the fall of each year have recently been identified to species (spring vs. summer Chinook) using DNA analysis. With the results of this analysis, captured Chinook parr were classified as either spring or summer Chinook.

We captured 487 wild yearling spring Chinook emigrants between 19 February and 30 June at the Methow River trapping location, with peak capture on 1 April $(N=56)$. Overall mortality of wild Chinook captured totaled three of the 487 fish captured ( $0.62 \%$ ). We PIT tagged 476 of the wild Chinook emigrants and released 471 after subtracting shed tags and mortalities. We also captured 3,339 hatchery Chinook at the Methow River trap, which included spring and summer races. Overall mortality of the hatchery Chinook captured totaled 74 fish (2.2\%).

We captured 179 emigrant Chinook parr between 1 October and 5 December with peak capture occurring on 2 November $(N=51)$. We DNA sampled 174 of the Chinook captured and conducted genetic analysis on 100 of these samples. One sample failed to amplify, of the remainder, 96 ( $97.0 \%$ ) were confirmed to be spring Chinook and 3 (3.0\%) were summer Chinook. We inserted PIT tags into 174 of the Chinook parr captured and released 173 parr after subtracting a single mortality.

No mark/recapture trials were conducted with Chinook smolts for the low position in the spring at the Methow trap because high discharge enabled the trap to operate in the upper position for most of the spring trapping season. Previous mark/recapture trials in the low position from previous years resulted in a significant relationship ( $P<0.01 ; \mathrm{r}^{2}=0.52$ ), and we used the regression parameters $(y=-2.57 \mathrm{E}-05 x+0.161723324)$ to determine estimates for the low trapping position in 2016. For the upper trapping position, we were able to conduct two mark/recapture trials with hatchery Chinook, and one trial with wild Chinook. Adding these groups to the previous years' model resulted in a significant relationship ( $P<0.01, r^{2}=0.75$; Table 4) and the regression parameters $(y=-2.52 \mathrm{E}-05 x+0.270693602)$ were used for this position in 2016 to determine estimates. Using both these flow models, the estimated number of yearling spring Chinook emigrants was $35,330( \pm 5,169,95 \% \mathrm{CI})$. When combined with the estimate of parr that emigrated past the trap in 2015 (34,402 $\pm 180,06195 \% \mathrm{CI}$ ), we estimated that 69,732 ( $\pm$ 180,135 95\% CI) 2014 brood wild spring Chinook migrated from the Methow River basin between 1 October 2015 and 30 June 2016 (Figure 3.1; Table 3.9). We did not attempt to estimate the contribution of spring Chinook fry that passed the Methow trap during the spring to basin-wide juvenile production.

Figure 3.1. Daily emigration of 2014 brood spring Chinook from the Methow River by life stage.

## Twisp Trap

Trapping at the Twisp River trap site (rkm 2) occurred between 19 February and 5 December 2016 using a rotary screw smolt trap with a 1.5 m cone diameter. Trapping at the Twisp site was interrupted on three occasions for a total of 35 days in 2016 because of high flow and debris. We captured 403 wild yearling spring Chinook emigrants at the Twisp trap between 27 February and 30 June. Peak capture occurred on 2 April ( $N=36$; Figure 3.2). We PIT tagged 397 wild yearling emigrants and no mortalities or shed tags were recorded. Overall mortality of wild yearling Chinook totaled one of the 403 fish captured ( $0.25 \%$ ). We also captured 2,177 hatchery spring Chinook and no mortality of these fish was recorded.

We captured 1,277 subyearling spring Chinook between 27 February and 5 December at the Twisp trap with peak capture occurring on 21 October ( $N=84$ ). Although most subyearling Chinook were too small for PIT tagging, we implanted 612 PIT tags into Chinook parr and no mortalities occurred although one shed tag was detected (Attachment A). Overall, four mortalities of subyearling Chinook occurred (0.31\%).

Two mark/recapture trials were conducted with hatchery spring Chinook smolts at the Twisp trap in the spring of 2016, but they could not be combined with historical groups to produce a
significant relationship. However, a significant efficiency discharge relationship existed from release groups conducted during previous seasons ( $P<0.01, \mathrm{r}^{2}=0.64$ ). Using the flow model regression parameters $(y=-0.00056877 x+0.529960351)$ derived from these trials, we estimated that 6,519 ( $\pm 1,561,95 \%$ CI) smolts emigrated from the Twisp River between 27 February and 30 June 2016. One redd was identified downstream of the Twisp trap in 2014 producing an estimated 48 migrants resulting in a total production estimate of 6,567 ( $\pm 1,566,95 \%$ CI) yearling Chinook smolts. An estimated 18,290 ( $\pm 4,747,95 \%$ CI) 2014 brood spring Chinook parr emigrated from the Twisp River in the fall of 2015 (Attachment A). In addition to the smolt trap estimates, mark/detection trials performed at the Twisp PIT tag array were used to estimate that 3,443 ( $\pm$ 1,272, 95\% CI) spring Chinook emigrated between 21 November 2015 and 26 February 2016 when the smolt trap was not operating. Adding an estimated 153 migrants from one redd below the trap resulted in a total estimate of 28,325 ( $\pm 5,167,95 \%$ CI) 2014 brood spring Chinook emigrants.

A single mark/recapture trial was conducted at the Twisp trap site in the fall of 2016. Combining this group with trials conducted in 2014 and 2015 showed that trap efficiency was significantly related to discharge ( $P<0.01, \mathrm{r}^{2}=0.57$ ), and the flow model regression parameters ( $y=$ $0.000908708 x+0.119169681$ ) were used to estimate that 13,831 ( $\pm 3,198,95 \% \mathrm{CI}) 2015$ brood spring Chinook salmon parr emigrated past the Twisp trap between 1 July and 5 December 2016. In addition, there were no Chinook redds observed below the Twisp trap site in 2015, so no expansion to account for migrants originating from downstream of the trap was necessary.

Table 3.9. Estimated emigrant-per-redd and egg-to-emigrant survival for Methow Basin spring Chinook. Methow Basin and Twisp River estimates are for redds deposited upstream and downstream of the respective trap sites, and include redds that dewatered. Rows identified with an asterisk include an estimate of over-winter emigration derived from a PIT tag array and added to the total number of emigrants. DNOT = Did not operate trap.

Figure 3.2. Daily emigration of 2014 brood yearling spring Chinook (YCW) from the Twisp River in 2016.

## PIT Tagging and Survival

Most wild juvenile Chinook captured at the Methow and Twisp smolt traps that were in good physical condition and had a fork length greater than 65 mm were PIT tagged prior to release. Within each release year, the number of PIT tagged spring emigrants released from each trap site was used to evaluate smolt to adult survival (SAR) of smolts leaving the Methow and Twisp river basins each spring. Adult detections of PIT tagged fish at Bonneville Dam were summed and divided by the number of juvenile salmonids tagged and released at the Methow and Twisp smolt traps to determine smolt to adult survival rates. In some cases, survival to Bonneville was inferred from PIT tag detections at upriver dams (i.e., a fish passed Bonneville without being detected). Mean SAR for wild Twisp and Methow spring Chinook smolts was $0.54 \%$ and $0.64 \%$, respectively for the 2003-2011 broods (Table 3.10). However, sample sizes for some release years and trap sites were likely too low to produce accurate estimates.

Table 3.10. Smolt to adult returns (SAR) by age at return for PIT tagged wild yearling spring Chinook smolts tagged and released from the Twisp and Methow smolt traps.

| Brood | Release year | Release $N$ | Age at return ( $N$ ) to Bonneville Dam |  |  | Total | SAR \% |

## In-stream PIT Tagging

Some natural origin juvenile spring Chinook were PIT tagged in each major subbasin in 2016 (Attachment B) to estimate population size, evaluate life-stage specific survival rates and estimate stray rates. Because natural origin juvenile spring Chinook rear for a single year prior to emigration, parr to smolt survival rates could be calculated for some of the parr tagged between 2010-2015 (Table 3.11). Cormack-Jolly-Seber (CJS) survival estimates were obtained from the Data Access Real Time (DART) website maintained by the University of Washington’s School of Aquatic and Fishery Sciences. Survival estimates for parr tagged in the Methow, Twisp, and Chewuch rivers ranged from $8 \%$ to $52 \%$ over the five years (2011-2015 tag years) for which emigration is complete (Table 3.11). Standard error (SE) values generated for individual estimates of some groups were high however, indicating that tag rates or capture probability was not high enough for some locations and years.

Table 3.11. In-stream PIT tagging and recovery at Rocky Reach Dam juvenile bypass (RRJ) detector of natural origin juvenile spring Chinook parr from the Methow, Twisp, and Chewuch rivers. Cormack-Jolly-Seber (CJS) survival estimates with standard error (SE) and probability of survival were obtained from the Data Access Real Time website (DART) maintained by the University of Washington's School of Aquatic and Fishery Sciences.

### 3.4 Spawning Ground Surveys

Spring Chinook spawning ground surveys were conducted in the Methow River basin between 2 August and 29 September 2016 (Attachment C). Surveys are intended to provide total redd counts within the Methow, Twisp, and Chewuch watersheds. Biological and geospatial information recovered from sampled carcasses provides the data necessary to evaluate spawning distribution and timing of hatchery and natural origin Chinook.

## Redd Counts

A total of 361 spring Chinook redds were constructed in the Methow Basin in 2016, lower than the overall mean number of redds found in the 2003-2015 spawning years (Table 3.12). Redd counts in most individual spawning areas were lower than the overall mean totals except for the WNFH outfall (Table 3.12). Within the 2016 spawning year, most redds were found in the Methow River and tributaries (64.0\%). The Chewuch and Twisp rivers accounted for $23.3 \%$ and $12.7 \%$ of Methow Basin redds, respectively.

Table 3.12. Spring Chinook redd count totals by spawning area and year in the Methow River Basin. Surveys were conducted in the primary tributaries, and in the Methow Hatchery (MH) and Winthrop National Fish Hatchery (WNFH) outlet channels.

| Year | Methow R. | Early <br> Winters Cr. | MH <br> outfall | WNFH <br> outfall | Lost R. | Twisp R. | Chewuch <br> R. | Total |

| Mean | 356 | 8 | 29 | 27 | 17 | 83 | 186 | 706 |

## Redd Distribution

The greatest number of spring Chinook redds within the Methow River basin were found in reach M9 of the Methow River, a nine km reach downstream of Weeman Bridge ( $N=75$; Table 3.13). This section typically has the highest annual redd count within the basin (Attachment C). Spawning in the Twisp River was primarily in section T7 (32.6\%) and in section C2 of the Chewuch River (29.2\%). Spawning was observed in Methow River tributaries (e.g., Early Winters Creek, Lost River), but no spawning tributaries have been identified in the Chewuch or Twisp river watersheds (Table 3.13).

Table 3.13. Spawning distribution (redd counts) and proportion of redds within primary tributaries and reaches of the Methow Basin in 2016.

## Spawn Timing

Fish were actively spawning in all three subbasins by the week starting on 14 August, and peak redd counts occurred earlier in the Methow subbasin than the Chewuch and Twisp subbasins (Table 3.14; Figure 3.3). Spawning in all subbasins was completed by late-September (Attachment C).

Table 3.14. Redd counts by subbasin and week starting date for spring Chinook spawning in the Methow, Twisp, and Chewuch subbasins in 2016.

| Subbasin | Week starting date (Sunday) |  |  |  |  |  |  |  |  | Total |

## Spawning Escapement

Spawning escapement values were derived by expanding redd counts by a fish-per-redd (FPR) value calculated from sampling the overall spring Chinook run at Wells Dam for origin, sex, and age composition. Based on the 2016 FPR value (1.93) there were an estimated 697 spawners in the Methow River basin in 2016, of which 320 (45.9\%) were estimated to be wild (NOR) fish (Table 3.15). Estimated spawning escapement does not include hatchery or wild fish collected for broodstock. Wild fish comprised $62.3 \%, 67.4 \%$, and $35.7 \%$ of the estimated spawning escapement in the Chewuch, Twisp, and Methow subbasins, respectively (Attachment C).

Table 3.15. Estimated spawning escapement by stream in the Methow River Basin in 2016.

## Carcass Sampling and Distribution

In general, all salmon carcasses encountered during spawning ground surveys were sampled for sex, age, origin, egg retention, hatchery marks and tags, and their location was recorded using hand-held GPS devices. Most carcasses recovered in the Methow river basin were hatchery origin fish, while most carcasses recovered in the Chewuch and Twisp River basins were natural origin fish (Table 3.17). Surveyors (WDFW and USFWS) sampled 36.0\% of the overall Methow Basin estimated spawning population in 2016 (Attachment C).

Egg retention was estimated for 133 of the 174 female carcasses examined. Using mean fecundities from MH broodstock (MetComp and Twisp), adjusting for mean egg-retention rates, and accounting for the proportion of hatchery and wild females by age class on the spawning grounds, an estimated total of 1,426,641 eggs were deposited in the Methow River basin in 2016 (Table 3.18).

## 3.5: Life History Monitoring

Adult returns to Wells Hatchery, Methow Hatchery, the Twisp River weir, and those recovered in fisheries and on spawning grounds were used to assess life history characteristics of spring Chinook stocks reared at Methow Hatchery.

## Age at Maturity

Methow River basin spring Chinook adults, regardless of origin, primarily return at age-4 (Table 3.19). Average age-4 returns across river basins ranged from $73-76 \%$ for hatchery fish and 72 $-77 \%$ for natural origin fish. Hatchery origin fish were more likely to return at age-3 and less likely to return at age-5 than natural origin fish, on average (Table 3.19).

Table 3.19. Proportion of adult returns by total age of the 1998-2010 broods of Methow Hatchery spring Chinook and Methow Basin natural origin Chinook. Data for hatchery origin fish (H) is derived from expanded CWT recoveries from broodstock, fisheries, and spawning grounds. Chewuch releases from the 1998 and 2000 broods are included in the Methow spring Chinook category for those years. Data for natural origin fish (W) is derived from expanded escapement estimates from spawning ground surveys.

| Brood year | Origin | Age at return |  |  | Total |
| :---: | :---: | :---: | :---: | :---: | ---: |
|  |  | Age-3 |  | Age-4 |  |

| Brood year | Origin | Age at return |  |  | Total |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Age-3 |  | Age-4 |  |

## Length at Maturity

Length at maturity of Methow Composite spring Chinook was similar to wild spring Chinook from the Methow and Chewuch Rivers (combined in Methow Composite category) for the longterm mean (1992-2010 broods; Table 3.20). Length at maturity of Twisp spring Chinook recovered in the Twisp River were similar to their wild counterparts of the same sex and age, although for both stocks, sample sizes for some sex, age, and origin comparisons were small.

Table 3.20. Mean post-eye to hypural plate ( POH ) length (cm) of adult Chinook Salmon by sex, age, origin, and release location (hatchery fish) or stream of recovery (wild fish). Adult data for Twisp wild fish includes those found on spawning ground surveys, retained for broodstock at the Twisp weir, and fish collected at Wells Dam for which stock was determined through genetic assessment. Wild fish collected from Fulton Dam are included in the Chewuch groups.

## Contribution to Fisheries

Spring Chinook released from Methow Hatchery were captured in ocean and Columbia River fisheries, but no freshwater fisheries upstream of Priest Rapids Dam have targeted spring Chinook except in the Wenatchee Basin. Additionally, because recent broods of Methow Hatchery spring Chinook have not been adipose fin-clipped, direct harvest should occur only in non-selective fisheries. Thus, estimates of overall harvest rates include non-selective fishery harvest and indirect harvest associated with catch-and-release mortality in selective fisheries. Harvest and catch-and-release mortality were estimated using ad-clipped and CWT'd surrogate stocks (e.g., Chiwawa, WNFH stocks) to estimate expected contribution rates of un-clipped (Methow Composite and Twisp) stocks to specific fisheries. Harvest and harvest-related mortality has been relatively high for some broods with four broods exceeding $44 \%$ harvest, and twelve exceeding 10\%, while mean harvest rates have been below $11 \%$ for all stocks (Table 3.21).

Table 3.21. Adult returns of coded-wire tagged Methow Hatchery spring Chinook by brood and release location. Recoveries are expanded by tag rate and sample rate, and include estimated impacts of post-release mortality in selective fisheries for adipose-present releases (broods 20002010). Releases that were not tagged to denote separate release locations (Methow and Chewuch 1998 and 2000 broods) were excluded, as were those where no releases occurred (1995 Chewuch and Twisp broods).

## Migration Timing

The 2016 spring Chinook migration to Wells Dam was monitored between 3 May and 24 June to evaluate the run composition and age structure of returning adults (Attachment C), and to facilitate hatchery broodstock collection. However, migration timing evaluations at Wells Dam represent pooled hatchery and wild stocks because individual hatchery stocks (e.g., Methow Composite, WNFH) have received the same external mark, and CWT's are typically not collected or extracted from fish sampled at Wells Dam. Using these data, wild fish (NOR) migrated to Wells Dam similarly to hatchery fish (HOR) within the age-3 and age- 4 classes, but age-5 wild fish migrated on average eight days earlier (Table 3.22). Comparisons of age-3 fish were not robust because of the small sample size of wild fish. Although the migration trend is typical, the arrival time at Wells Dam was closer for hatchery and wild fish from the 2010-2015 broods, than for the 2006-2009 broods, and mean arrival time in 2015 was the earliest in the past decade, most likely due to low flow conditions in the Columbia River during the adult migration period (Figure 3.4).

Table 3.22. Mean migration date of hatchery (H) and wild (W) spring Chinook to Wells Dam by age and percentile of the overall age-class return in 2016. Totals do not include fish of unknown origin or age.

Figure 3.4. Mean (+/-95\% CI) arrival day of the year at Wells Dam of hatchery and wild spring Chinook by return year.

## Straying

Targets for strays based on return year (recovery year) within the Methow River sub-basin should be less than $10 \%$ and targets for strays outside the Methow River sub-basin should be less than $5 \%$. The target for brood year stray rates should be less than $5 \%$.

The percentage of the spawning escapement made up of hatchery-origin Chewuch and Twisp released spring Chinook in non-target spawning areas within the Methow River sub-basin has been high in most years and exceeded the target of $10 \%$ for return year and $5 \%$ for brood year. Conversely, adult returns from Methow River (on-station) releases rarely strayed into non-target recipient populations (Table 3.23). Methow Hatchery spring Chinook have constituted less than $5 \%$ of the spawning escapement by return year of other spring Chinook populations (Table 3.24).

Table 3.23. Straying by Methow Hatchery spring Chinook released as yearling smolts by brood year, release location, and recipient area.

| ${ }^{\text {a }}$ Fish |  |  |  |

${ }^{a}$ Fish was recovered during WDFW genetic study trapping and was not included in spawning escapement estimate.
Smolt to Adult Survival and HRR

The overall smolt-to-adult return of Methow Hatchery spring Chinook stocks was calculated from expanded CWT recoveries including and excluding harvested fish. Overall, SAR (including harvested fish) averaged $0.22 \%, 0.33 \%$, and $0.22 \%$, respectively for Twisp, Methow, and Chewuch river releases (Table 3.25). Survival (SAR) of 2010 brood fish was above the overall mean value for all populations in the Methow River Basin. Similarly, HRR values calculated as the number of adult returns (including harvest) divided by the number of adult broodstock, were also higher than average for all 2010 brood releases, but most Methow Basin release groups had overall mean HRR values below the target value of 4.5 (Table 3.25).

Table 3.25. Smolt to adult return (SAR) and hatchery replacement rate (HRR) of Methow Hatchery spring Chinook stocks by brood year. Methow River brood years 1998 and 2000 represent combined Methow and Chewuch River releases. Number of broodstock includes all fish collected regardless of fate, including mortalities and fish not used.

## Natural Replacement Rates

The NRR of wild spring Chinook in the Methow River basin was calculated as the number of natural origin recruits (returning adults) divided by the overall naturally spawning population of hatchery and natural origin adults of the parent brood (Attachment C). The NRR of the last brood for which complete adult return data were available (2010 brood) was $<1$ and similar to the overall median NRR values in all three subbasins (Table 3.26).

Table 3.26. The Natural Replacement Rate (NRR) of Methow Basin spring Chinook populations by year and primary spawning subbasin. The NRR is calculated by dividing the number of natural origin return (NOR) recruits produced by the sum of the spawning population of hatchery- and natural-origin spawners (Est. spawning escapement).

| Parent <br> brood | Est. spawning escapement | Return age |  |  | Total expanded recruits (NOR) | NRR | HRR |

## Proportionate Natural Influence

The Hatchery Scientific Review Group (HSRG) developed guidelines for salmon and steelhead hatchery programs intended to provide a foundation of hatchery reform principles that should aid hatcheries in the Pacific Northwest in meeting conservation and sustainable harvest goals (HSRG 2008). These guidelines provide a means of indexing the genetic risk of hatchery programs to natural populations by calculating the proportionate natural influence (PNI) of a population. The PNI is calculated as: (the proportion of natural origin fish within the broodstock [pNOB] $) /(\mathrm{pHOS}+\mathrm{pNOB})$. A PNI value $>0.5$ indicates that genetic selection pressures from the natural environment have a stronger influence on the population than those from the hatchery environment. A PNI value $\geq 0.67$ was recommended for conservation programs by the HSRG (2009). Data necessary to calculate PNI values are derived from spawning ground surveys (i.e., pHOS; Attachment C) and from hatchery broodstock sampling (i.e., pNOB; Attachment C). For the 2003-2016 broods, mean PNI was higher in the Twisp Basin than in the Methow or Chewuch river basins (Table 3.27). However, values for all basins are low and indicate that most genetic selection pressure on progeny produced from naturally spawning adults comes from the hatchery environment (Table 3.27).

Table 3.27. The proportion of natural influence (PNI) calculated for specific broods of spawning spring Chinook in the Methow River basin. The PNI was calculated as: $\mathrm{pNOB} /(\mathrm{pNOB}+\mathrm{pHOS})$.

## Section 4: Wells Hatchery Summer Chinook Salmon

This section focuses on the last brood for which hatchery releases were completed during the report year ( 2014 brood) and includes data from historic broods where appropriate. Broodstock for the Wells Hatchery summer Chinook Salmon program are primarily collected from the Wells Hatchery volunteer channel trap, but natural origin fish have also been retained from the West Fish Ladder at Wells Dam in some years. Broodstock collected from these sources have been used for multiple programs in addition to the Wells Hatchery yearling and subyearling releases. These programs include the Turtle Rock Hatchery yearling and subyearling programs, Lake Chelan sport fish enhancement program, and reintroduction programs in the Entiat and Yakima rivers. Because broodstock for these various programs are from the same collection location, most adult-based metrics (e.g., extraction rate, length at age, sex composition, etc.,) include all broodstock spawned, regardless of program. However, fecundity and ELISA values are generated solely from female Chinook spawned for the Wells yearling program because individual females for subyearling programs are not typically incubated separately to allow individual fecundity estimates and the relatively short rearing period for subyearling program fish negates the need for virology sampling of adult females.

## 4.1: Broodstock Collection and Sampling

Trapping of the 2014 brood of Wells Hatchery summer Chinook Salmon occurred between 7 July and 29 August, 2014. During this time a total of 2,098 hatchery origin and 29 wild origin fish were collected. The overall collection represented $25 \%$ of the summer Chinook Salmon escapement between the Wells and Rocky Reach Dams based on the difference between the total summer Chinook Salmon counts at each dam. Most fish collected have historically been used for broodstock purposes, but recent collections of adult fish have included surplus fish provided to local tribes (Table 4.1).

Table 4.1. Collection of summer Chinook Salmon at Wells Hatchery and the prespawn mortality (PSM), surplus mortality (Mort), spawning (Spawn), release (Rel.) and tribal surplus totals by brood and fish origin (hatchery or wild). Released fish for the 1998-1999 broods are listed as hatchery origin by default. Fish for which the origin or disposition (PSM, Spawn, etc.) are unknown are included in the hatchery total for each brood.

| Brood year | Wild Chinook Salmon |  |  |  |  | Hatchery Chinook Salmon |  |  |  |  |  | Total spawned |

## Length and Age at Maturity

Most summer Chinook Salmon collected at Wells Hatchery are age-5 hatchery origin fish (Table 4.2). Within return years, wild fish generally have a greater mean fork length than hatchery origin fish of the same sex and age, although sample sizes of wild fish within these categories are often very small. For the 2014 return year, age- 4 and age- 5 fish were $52 \%$ and $43 \%$ of the total fish sampled, respectively. Natural origin fish within this return year had a greater mean fork length than hatchery fish of the same sex and age for most comparisons but sample sizes of wild fish were very low, precluding robust comparisons for all sex, age, and origin groupings (Table 4.2).

Table 4.2. Mean fork length (cm), number ( $N$ ), and standard deviation (SD) by sex, age, origin, and return year of summer Chinook Salmon retained for broodstock at Wells Hatchery. Age-2 and age-7 fish are excluded because too few fish are within these categories to facilitate statistical comparisons.

## Sex Ratio and Fecundity

The long-term mean sex ratio of fish retained for broodstock (excludes released fish) favored females (Table 4.3), and the sex ratio of the 2014 brood was slightly more skewed towards
female fish than the average. Of the 2014 brood female Chinook sampled, overall fecundity $(4,293)$ was less than the long-term mean fecundity (Table 4.3), and less than the mean fecundity value $(4,475)$ used to estimate broodstock collection quotas in the broodstock collection protocols. Fecundity data from the 2014 brood was only collected from hatchery origin females because no wild females were spawned for the Wells yearling Chinook program.

Table 4.3. Sex ratio (Male/Female) and mean fecundity by return year and origin of summer Chinook Salmon retained for broodstock at Wells Hatchery. NS = not sampled.

| Return year | Hatchery Chinook Salmon |  |  |  | Wild Chinook Salmon |  |  |  | Overall |  |

## ELISA Monitoring

Adult female Chinook Salmon spawned for yearling-release programs are screened for the presence of Bacterial Kidney Disease (BKD) using an ELISA assay. Results of this test are grouped into four general categories based on the optical density (OD) of each sample. Overall, $95 \%$ of OD values from sampled females have been in the Below-low category. For the 2014 brood, two females had OD values in the High category (Table 4.4), but all other sampled females were in the Below-low category. Eggs from both High ELISA females were culled prior to hatching.

Table 4.4. Enzyme-linked immunosorbent assay (ELISA) test results (\% of sampled fish) by return year and ELISA category for female summer Chinook Salmon spawned at Wells Hatchery for yearling-release programs.

## 4.2: Within-hatchery Monitoring

## Juvenile Marking and Tagging

Juvenile summer Chinook Salmon at Wells Hatchery are marked with an adipose-fin clip and tagged with a CWT prior to release. Mark retention sampling conducted prior to release in each year indicates that overall retention of applied marks and tags averaged $97.4 \%$ and $95.2 \%$ for subyearling and yearling program fish, respectively (Table 4.5). Summer Chinook Salmon for both programs are released directly from Wells Hatchery into the Columbia River. Yearling program fish are released in mid-April while subyearling program fish have historically been released in mid-June. However, a study (Snow 2015) conducted with the 2003-2007 broods of subyearling program fish determined that release-to-adult survival could be improved through earlier release (mid-May) of these fish, and thus the release time for subyearling fish was changed to mid-May beginning with the 2008 brood (2009 release; Table 4.5).

The overall mean number of fish released has been slightly higher than the release goal of 320,000 for yearling program fish, and lower than the 484,000 goal for the subyearling program fish. Releases of 2014 brood fish were similar, with subyearling program fish below the goal and yearling program fish above the release goal, although releases of both groups fell within $\pm$ $10 \%$ of the release goals (Table 4.5).

Table 4.5. Pre-release marking and tagging of Wells Hatchery summer Chinook by brood year and program. All CWT codes are prefaced by the two-digit WDFW agency code "63". All fish also received an adipose fin-clip prior to release, and the mark rate represents the proportion of total fish released that successfully retained both the mark and tag.

| Brood year | Subyearling Chinook Salmon |  |  |  | Yearling Chinook Salmon |  |  |  |

## Juvenile Size and Condition at Release

Size-at-release fork length and weight targets for DCPUD program fish are described in Murdoch et al. (2012). The 2014 brood yearling program fish were $101 \%$ of the target release fork length goal. Mean size-at-release of the 2014 brood subyearling program fish was 80.2 mm , but specific size-at-release targets for this program have not yet been developed that reflect the earlier release date initiated with the 2008 brood (Table 4.6). The coefficient of variation (CV) for the 2014 brood subyearling and yearling programs were at or below the yearling-release target value of nine.

Table 4.6. Mean fork length (mm), weight (g), coefficient of variation (CV), standard deviation (SD), and condition factor (K) of Wells Hatchery summer Chinook Salmon by release type and brood year prior to release. Data for subyearling program fish from the 1998-2007 broods are from mid-June release groups, and data from the 2008-2014 broods are from mid-May releases.

| Brood | Fork length (mm) |  |  | Weight (g) |  |  |  | K |

## Survival Estimates

In-hatchery survival from fertilization to release of the 2014 brood fish was greater than the target value for both the subyearling and yearling releases (Table 4.7). Subyearling survival was lower than target values for most of the post-ponding categories, while yearling program fish were above survival targets in all categories. Yearling program fish typically did not meet unfertilized-egg-to-release survival targets in years when egg losses were higher than usual, while subyearling program fish were usually below the target value because of losses after ponding.

Table 4.7. Survival (\%) of Wells Hatchery summer Chinook Salmon by brood and survival category. Adult survival (collection to spawning) for each brood is listed under the yearling program.

| Brood | $\begin{gathered} \hline \text { Colled } \\ \text { spav } \end{gathered}$ | ion to | Unfertilized egg-eyed | Eyed eggponding | 30 d after ponding | 100 d after ponding | Ponding to release | Transport to release | Unfertilized egg-release |

## 4.3: Life History Monitoring

Because the Wells summer Chinook Salmon program is a harvest augmentation program and not a conservation program, monitoring life history traits in relation to those of a natural population is not appropriate. However, assessing life history monitoring indicators such as age at return, length at return, and sex ratio at return is valuable from a management perspective to assess stock-specific factors that may affect broodstock collection, fecundity, and other in-hatchery metrics. Adult returns to Wells Hatchery and those recovered in fisheries and on spawning grounds were used to assess life history characteristics of Wells yearling and subyearling summer Chinook Salmon releases.

## Age at Maturity

Wells Hatchery summer Chinook Salmon are considered a segregated harvest program where comparisons between the hatchery stock and naturally-produced fish are not applicable.

Releases of subyearling fish from the 2009 brood returned primarily as age-4 adults, while those released as yearlings returned about equally at age-4 and age-5 (Table 4.8). Overall, yearling fish typically had an older total age at return than subyearling program fish, but subyearling fish spent more of their life in saltwater (Figure 4.1).

Table 4.8. Proportion of adult returns by total age of the 1992-2009 broods of Wells Hatchery summer Chinook Salmon released as subyearling or yearling migrants. Data is from RMIS recovery of CWTs in the broodstock, freshwater fisheries (sport, commercial, and tribal), and spawning ground categories, although juvenile fish captured within their year of release were excluded.

| Brood year | Release type | Age-2 | Age-3 | Age-4 | Age-5 | Age-6 | Age-7 | Total |

Figure 4.1. Mean salt water age of Wells Hatchery summer Chinook Salmon from the 19922009 broods released as subyearling or yearling program fish. Adult returns are from broodstock, spawning ground, or freshwater sport, commercial, and tribal fisheries.

## Length at Maturity

Because Wells summer Chinook Salmon are considered a segregated harvest program, comparisons between the hatchery stock and naturally-produced fish are not applicable. Lengths of returning yearling and subyearling releases by age were collected primarily from broodstock fish spawned at Wells Hatchery and are presented in Table 4.9. Juvenile Chinook Salmon
released as subyearlings had a greater mean POH length at younger adult return ages than juveniles released as yearlings, but the differences decreased as age-at-return increased (Figure 4.2).

Table 4.9. Mean post-eye to hypural plate ( POH ) length ( cm ), number ( $N$ ), and standard deviation (SD) of adult returns by sex and total age of subyearling and yearling Chinook Salmon releases from Wells Hatchery from the 1993-2009 broods.

Figure 4.2. Mean (+/- 95\% CI) POH length (cm) of adult returns of summer Chinook Salmon released as subyearling or yearling fish from the 1992-2009 broods.

## Contribution to Fisheries

Based on expanded CWT recoveries, most Wells Hatchery summer Chinook Salmon prior to 2002 were captured in ocean fisheries, regardless of release type (Table 4.10). However, for the last five broods for which complete adult return data are available (2005-2009), harvest was primarily in freshwater fisheries for subyearling releases (36\% freshwater; 31\% ocean).
Yearling releases were primarily captured in ocean fisheries (31\% freshwater; 35\% ocean; Table 4.10), but freshwater fishery extraction has been increasing (Figure 4.3). This change is primarily attributable to increases in freshwater sport and tribal harvest rates.

Figure 4.3. Cumulative retention of Wells summer Chinook Salmon by brood year in commercial, sport, and tribal fisheries in ocean and freshwater areas.

## Straying

Because the Wells Hatchery summer Chinook Salmon program is a harvest augmentation programs and not a conservation program, all spawning ground recoveries were considered to be in non-target (i.e., stray) areas. Adult fish collected from the Wells Hatchery volunteer fish ladder were not considered strays, but the east and west fish ladders at Wells Dam were categorized as non-target recipient hatchery areas because trapping in those locations target Methow and Okanogan river stocks. However, recent broodstock collections in those locations only target adipose-present fish, thus excluding Wells adipose-clipped fish. Overall, stray rates from adult return of subyearling and yearling releases from the 1992-2009 broods averaged $7.4 \%$, slightly above the $5 \%$ target value (Table 4.11). Returns from Wells releases seldom constituted greater than $5 \%$ of the spawning escapement by return year of other recipient summer Chinook populations, with the exception of the Chelan River, which is not considered an extant population (Table 4.12).

Table 4.11. Straying by Wells Hatchery summer Chinook Salmon released as subyearling and yearling smolts by brood year and recipient stray category.

| Brood year | Total brood return | Recipient category |  |  | \% stray |

## Smolt to Adult Survival and HRR

The smolt-to-adult return of Wells summer Chinook Salmon yearling and subyearling program fish was calculated from expanded CWT recoveries and averaged $1.1 \%$ and $0.1 \%$, respectively (Table 4.13). The mean HRR, calculated as the number of adult returns divided by the number of adult broodstock, was also much greater for yearling releases (19.9) than for subyearling releases (2.2). Yearling releases on average were greater than the M\&E Plan HRR target of 5.3, while subyearling releases were equal to the M\&E Plan HRR target of 2.2. For the latest brood for which adult return information is expected to be complete (2009 brood) the HRR rate was above expected values for both release groups.

Table 4.13. Smolt-to-adult survival (SAR) and hatchery replacement rate (HRR) of Wells summer Chinook Salmon released as yearling and subyearling smolts by broodyear.

## Section 5: Wells Hatchery Summer Steelhead

This section focuses on the last brood for which releases were completed during the report year (2015 brood) and includes data from historic broods where appropriate. Broodstock for the Wells Hatchery summer steelhead program are primarily collected from the fish ladders at Wells Dam, or more recently, from the Twisp River Weir and the outfall channels at the Methow (WDFW) and Winthrop (USFWS) fish hatcheries. Returning adult steelhead from the Wells Hatchery Complex programs support salmon recovery goals and provide harvest opportunities in years of high abundance.

## 5.1: Broodstock Collection and Sampling

Trapping of the 2015 brood of Wells Hatchery summer steelhead occurred between 6 August and 9 November 2014 at Wells Dam. During this time a total of 191 adipose fin-clipped hatchery origin fish were retained, representing $5.3 \%$ of the estimated adipose fin-clipped hatchery fish returning to Wells Dam during the trapping period. Overall, pre-spawn mortality totaled $0.4 \%$ of the total hatchery fish collected. In addition to fish collected at Wells Dam, broodstock were also collected from the Twisp River weir, the Omak Creek weir, and from the Methow Hatchery outfall channel. Spring 2015 trapping at the Twisp River weir and the Methow Hatchery outfall provided 30 and 37 hatchery origin fish for Wells Hatchery safety-net programs, respectively. Natural origin fish were also retained from the Twisp River weir for the Twisp River conservation program, and no pre-spawn mortalities were recorded from broodstock collected at tributary sites (Table 5.1).

Table 5.1. Collection of summer steelhead at Wells Hatchery and the prespawn mortality (PSM), surplus mortality (Mort), spawning (Spawn), and release (Rel.) totals by brood and fish origin (hatchery or wild). Table excludes fish released prior to the implementation of spawning.

## Age at Maturity

Most summer steelhead collected for Wells Hatchery broodstock were fish that had spent a single winter in salt water before returning to Wells Dam (1-salt; Table 5.2). The overall mean proportion of 1-salt and 2-salt fish was similar between hatchery and natural origin fish, although differences within years were observed. Broodstock collected at the Twisp River weir were typically natural origin fish, and were mostly 2-salt fish on average, similar to the 2015 brood age ratio (Table 5.2). Hatchery origin fish collected for broodstock at the Twisp River weir in 2015 were equally represented by 1-salt and 2-salt fish, although not all the collected fish were spawned for the Twisp program.

Table 5.2. Proportion of hatchery and wild steelhead by saltwater age retained for broodstock for Wells Hatchery or Twisp River (T) programs.

| Brood | Hatchery |  |  | Wild |  |  |

## Sex Ratio and Fecundity

The overall mean sex ratio of the steelhead retained for broodstock (excludes released fish) favored females regardless of fish origin or collection location (Table 5.3). The sex ratio of the 2015 brood was skewed towards female fish regardless of origin, although comparisons between wild and hatchery fish could not be made at most locations because broodstock collections generally targeted either hatchery or wild fish (Table 5.3). Of the female fish spawned, fecundity of the 2015 brood was generally higher than overall mean values for hatchery and wild females by collection location and above mean values used in broodstock protocol calculations for hatchery $(6,022)$ and wild $(5,737)$ females for most locations (Table 5.3).

Table 5.3. Sex ratio (Male/Female) and mean fecundity by return year and origin of summer steelhead spawned for the Wells, Twisp River, Okanogan, and Omak Creek programs.

| Brood year | Hatchery steelhead |  |  |  | Wild steelhead |  |  |  | Overall |  |

## 5.2: Within-hatchery Monitoring

## Juvenile Marking and Tagging

Juvenile releases from the 2015 brood were above the overall release goal of 408,000 fish for PUD programs (Tonseth 2014), but releases in all locations were within $10 \%$ of the release goals (range 98\%-109\%) except for Twisp River releases (121\%; Table 5.4). The overall release goal was slightly above the target (108\%) because releases into the Twisp, Columbia, and Okanogan rivers were slightly above target values. Steelhead releases into the Okanogan River basin from the 2015 brood were marked and tagged with adipose fin-clips, and coded- and blank-wire tags in the snout or in the caudle peduncle in various combinations to evaluate mark and tag loss. Twisp River releases received a snout CWT, but were not adipose fin-clipped (Table 5.5). All other fish released by Wells Hatchery were marked with an adipose fin-clip but were not tagged prior to release.

Table 5.4. Release of Wells Hatchery complex summer steelhead by brood year and release stream. Release values include fish transferred to other agencies for acclimation purposes (e.g., Omak Creek).

## Juvenile Size and Condition at Release

Size-at-release fork length and weight targets for DCPUD program fish are described in Murdoch et al. (2012). The 2015 brood Wells and Twisp program fish were $105.6 \%$ and $87.9 \%$ of the target release fork length goal, respectively (Table 5.6). Coefficient of variation (CV) of fork length for Wells 2015 brood releases was higher than the target value of nine for both Wells and Twisp program releases.

Table 5.6. Mean fork length (mm), weight (g), coefficient of variation (CV), standard deviation (SD), and condition factor (K) of Wells Hatchery complex summer steelhead by stock and brood year prior to release. An asterisk denotes a sample collected at time of transfer to an acclimation pond instead of immediately prior to release. SN = safety-net program.

| Brood | Stock | Fork length (mm) |  |  | Weight (g) |  |  |  | K |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Survival Estimates

Collection to spawning survival of adult broodstock has historically been above target levels, and survival of the 2015 brood adults for all programs was above 99\% (Table 5.7). Survival from eyed egg to ponding was below target levels for all 2015 brood programs, but survival values for most other categories were above target levels. Transportation to release values for the 2015 brood were calculated for the Methow Hatchery release group (Wells program; Table 5.7), St. Mary’s Acclimation Pond (Omak program; Table 5.8), and the Twisp River Acclimation Pond (Twisp program; Table 5.7).

Table 5.7. Survival (\%) of Wells Hatchery and Twisp River summer steelhead by brood and survival category.

| Brood | Collec spaw | ion to ning | Unfertilized egg-eyed | Eyed eggponding | 30 d after ponding | 100 d after ponding | Ponding to release | Transport to release | Unfertilized egg-release |

### 5.3 Natural Origin Juvenile Productivity

Smolt trapping was conducted in 2016 in the Methow and Twisp Rivers to estimate the productivity (smolts per redd) of steelhead spawning in the Methow and Twisp river basins. Because steelhead juveniles spend an extended period of time rearing in freshwater prior to migrating seaward, smolts captured each spring from these rivers represent multiple broods of spawning adults. Complete productivity estimates, therefore, require multiple years of smolt monitoring.

## Emigrant and Smolt Estimates

## Methow Trap

Trapping at the Methow River trap site (rkm 30) occurred between 19 February and 5 December 2016 using smolt traps with a 1.5 m or 2.4 m cone diameter. These traps were operated in two different trapping positions depending on the river discharge at the site. Trapping at the Methow
site was interrupted on two occasions for a total of 17 days because of high flow and debris. Steelhead production estimates were based on daily capture of wild steelhead emigrants, expanded by the estimated trap efficiency derived from a trap efficiency/flow model developed for each trap configuration (Attachment A).

We captured 190 wild summer steelhead emigrants (smolt and transitional) between 19 February and 30 June in the Methow River trap, with peak capture on 2 April ( $N=26$ ). We PIT tagged 179 wild steelhead emigrants and no shed tags or mortalities were recorded. Overall mortality of emigrant steelhead totaled one of the 190 fish captured ( $0.53 \%$ ). We also captured 473 hatchery steelhead juveniles at the Methow River trap, and no mortalities occurred.

We captured 23 wild fry and 112 wild summer steelhead parr during trapping in 2016 at the Methow trap site. Steelhead parr greater than 65 mm and in good physical condition were PIT tagged ( $N=104$ ), and 103 were releases after subtracting a single mortality. Overall mortality of fry $(N=1)$ and parr $(N=1)$ totaled $(1.5 \%)$ of the total fry and parr captured.

Due to low capture numbers of migratory steelhead, no mark/recapture trials were conducted with steelhead in 2016 at the Methow trap. Because no significant regression model existed for steelhead, we used the yearling Chinook flow models to estimate steelhead production for each trap position. Combining estimates from all positions, we calculated that 16,943 ( $\pm 4,393$, $95 \%$ CI) summer steelhead emigrated from the Methow River basin. However, an additional 696 migrants were estimated from redds located downstream of the trap in 2012 through 2015, which resulted in a total estimated migration of $17,639( \pm 4,482,95 \% \mathrm{CI})$ summer steelhead from the Methow River basin in 2016. We estimated the entire 2012 brood migration to be 25,726 ( $\pm$ 4,629, $95 \%$ CI) fish, including 392 migrants that were expected from redds $(N=9)$ located downstream of the Methow trap in 2012. The mean number of emigrants (smolts) produced per redd in the Methow Basin for the 2003-2012 broods was 19 (Table 5.9).

## Twisp Trap

Trapping at the Twisp River trap site (rkm 2) occurred between 27 February and 5 December 2016 using a rotary screw smolt trap with a 1.5 m cone diameter. Trapping at the Twisp site was interrupted on three occasions for a total of 35 days between 27 February and 5 December because of high flow and debris. Steelhead production estimates were based on daily capture of wild steelhead emigrants, expanded by the estimated trap efficiency derived from a trap efficiency/flow model developed for each trap configuration (Attachment A).

We captured 160 wild summer steelhead emigrants at the Twisp trap between 27 February and 30 June. Peak capture occurred on 2 April ( $N=21$ ). We PIT tagged 139 wild steelhead emigrants and no shed tags or mortalities were recorded (Attachment A). Non-migrant summer steelhead captured at the Twisp trap included 51 wild fry and 276 wild parr. We PIT tagged 242
steelhead parr with a fork length greater than 65 mm and no shed tags or mortalities were detected. Overall mortality of fry $(N=0)$ and parr $(N=1)$ represented $0.31 \%$ of the total fry and parr captured $(N=327)$. Wild summer steelhead parr had a mean fork length of 102.7 mm . A total of 2,100 juvenile hatchery summer steelhead were captured at the Twisp River trap and no mortalities were recorded.

Numerous mark/recapture trials were conducted with wild summer steelhead at the Twisp site in 2016, but none of them contained more than 35 fish. A flow efficiency relationship from previous years' release groups was used to estimate steelhead emigration at the Twisp site in 2016. The flow model regression ( $y=-0.00029758 x+0.410040455 ; P<0.01, \mathrm{r}^{2}=0.52$ ) was used to estimate that $5,132( \pm 1,733,95 \% \mathrm{CI})$ wild summer steelhead migrated past the Twisp River trap between 27 February and 30 June 2016. An additional 594 migrants were estimated from redds located downstream of the trap in 2012 through 2015, which provides a total estimated migration of 5,726 ( $\pm 1,831,95 \%$ CI) summer steelhead from the Twisp River in 2016. Most 2016 migrants were age-2 fish (74.6\%) from the 2014 brood (Table 5.8). Combining numbers from the last four years, the entire 2012 brood migration is estimated to be 5,882 ( $\pm$ $1,514,95 \% \mathrm{CI}$ ) fish, which includes 446 expected migrants produced from redds ( $N=10$ ) that were identified downstream of the Twisp trap in 2012. The mean number of emigrants (smolts) produced per redd in the Twisp Basin for the 2004-2012 broods was 38 (Table 5.10).

Table 5.9. Estimated emigrant-per-redd and egg-to-emigrant survival of Methow Basin steelhead. Methow Basin estimates are for redds deposited upstream and downstream of the trap site. Emigrant-per-redd values were not calculated for incomplete brood years.

## PIT Tagging and Survival

Most wild juvenile steelhead captured at the Methow and Twisp smolt traps that were in good physical condition and had a fork length greater than 65 mm were PIT tagged prior to release. Within each release year, the number of PIT tagged emigrants (smolt and transitional fish) released from each trap site were used to evaluate smolt to adult survival (SAR) of smolts leaving the Methow and Twisp river basins each spring. Adult detections of PIT tagged fish at Wells Dam were summed and divided by the number of juvenile salmonids tagged and released at the Methow and Twisp smolt traps by species to determine smolt to adult survival rates. Mean

SAR for wild Twisp and Methow steelhead smolts was $1.18 \%$ and $1.07 \%$, respectively for the 2006-2014 release years (Table 5.11). However, sample sizes for some release years and trap sites were likely too low to produce accurate estimates.

Table 5.11. Smolt to adult returns (SAR) by salt age for PIT tagged wild steelhead smolts tagged and released from the Twisp and Methow smolt traps.

## In-stream PIT Tagging

Natural origin juvenile steelhead were primarily PIT tagged in the Twisp subbasin in 2016 (Attachment B) to evaluate population size, life-stage specific survival rates, and to complete sampling requirements of an on-going relative reproductive success study of steelhead in the Twisp River. Because natural origin juvenile steelhead may rear for multiple years in freshwater
prior to emigrating, parr to smolt survival rates may be incomplete for fish tagged in recent years. Survival to detection at Rocky Reach Dam juvenile bypass was similar for tag groups between basins, although sample sizes for some years and locations were low (Table 5.12).

Table 5.12. In-stream PIT tagging and recovery at Rocky Reach Dam juvenile bypass detector of natural origin juvenile summer steelhead (SHR) from the Methow, Twisp, and Chewuch rivers. Cormack-Jolly-Seber (CJS) survival estimates with standard error (SE) and probability of survival were obtained from the Data Access Real Time website (DART) maintained by the University of Washington's School of Aquatic and Fishery Sciences.

### 5.4 Spawning Ground Surveys

Steelhead spawning ground surveys were performed to estimate the relative abundance, distribution, and timing of spawning within the Methow River basin (Attachment D). Surveys
were conducted between 4 March and 3 June 2016 in the Twisp River and in the Methow River between about the town of Winthrop and the confluence with the Columbia River. Some smaller sections of tributaries were also surveyed if spawning areas existed downstream of active PIT tag arrays.

## Escapement estimates

Overall, a total of 1,814 steelhead were estimated to have spawned in the Methow River Basin in 2016 (Table 5.13), with most spawners found in the Lower Methow subbasin ( $N=925$ ). The 2016 escapement estimates were derived from redd counts and from PIT tag detections at arrays located throughout the Methow Basin (Attachment D). Escapement estimates in the upper Methow and Twisp rivers were lower than the overall mean values, while lower Methow and Chewuch river escapement estimates were above overall mean values (Table 5.11).

Table 5.13. Estimated steelhead escapement by sample year for the four major subbasins in the Methow River watershed. Upper and Lower Methow subbasins are divided by the Highway 20 bridge in Winthrop, Washington. Lower Methow escapements combine PIT-based estimates and redd count estimates expanded by fish per redd values.

| Sample year | Steelhead escapement |  |  |  | Total |

| 2014 | 340 | 534 | 237 | 336 | 1,447 |
| 2015 | 394 | 1,217 | 629 | 300 | 2,540 |
| 2016 | 178 | 925 | 403 | 308 | 1,814 |
| Mean | 645 | 560 | 522 | 284 | 2,011 |

## Redd Distribution

Because most of the spawning escapement of steelhead in 2016 was determined through the use of PIT tag arrays, assessing redd distribution by stream reach is not possible for most spawning areas (Attachment D). Based on spawning escapement estimates from stream surveys and PIT tag expansions in the Lower Methow subbasin, tributaries such as Gold Creek and Beaver Creek were important spawning areas (Table 5.14). In the Twisp River, most redds were found in the mainstem, and relatively few redds were found in tributary sections (Table 5.15).

As part of an on-going reproductive success study in the Twisp River, female steelhead captured and release upstream of the Twisp River weir received a Floy tag and an abdominal-planted PIT tag prior to release. Additionally, some steelhead in 2016 were radio-tagged prior to release and tracked to spawning locations. Subsequent observations of Floy-tagged or radio-tagged fish on the spawning grounds, or detection of PIT tags in completed redds allowed us to evaluate the spawning distribution of hatchery and wild steelhead in the Twisp River. Using these methods, we were able to determine female origin for five of 33 redds (15\%) based on Floy tag or radiotelemetry detections. Wild female steelhead spawned farther upstream than hatchery steelhead females in 2016 but no significant differences were found in spawning location between hatchery and wild females from 2009 to 2016 (Goodman et al. 2017; Figure 5.1).

Table 5.14. Lower Methow River steelhead escapement estimates based on redd counts or PIT tags by reach. Redd totals in Methow River mainstem reaches (MRW1-8) are direct counts only; escapement for this area is derived from PIT-based escapement estimates (Truscott et al. 2017) using 1.92 fish per redd. Ns = not surveyed.

| Stream (description) | Code | Redds | Estimated escapement |  |

Figure 5.1. Mean spawning location (rkm; center point) and 95\% CI (whiskers) by origin of female steelhead released upstream of the Twisp River weir based on PIT tag detections and Floy tag observations in $2009(\mathrm{H}=45 ; \mathrm{W}=19)$, $2010(\mathrm{H}=40$; $\mathrm{W}=27)$, $2011(\mathrm{H}=26$; $\mathrm{W}=20)$, $2012(\mathrm{H}=10 ; \mathrm{W}=19), 2013(\mathrm{H}=5 ; \mathrm{W}=7), 2014(\mathrm{H}=8 ; \mathrm{W}=18), 2015(\mathrm{H}=11 ; \mathrm{W}=11)$, and $2016(\mathrm{H}=2 ; \mathrm{W}=3)$.

## Spawn Timing

Steelhead spawn timing was assessed as part of an on-going reproductive success study in the Twisp River. Female steelhead captured and release upstream of the Twisp River weir received an external Floy tag prior to release. Additionally, some steelhead in 2016 were radio-tagged prior to release and tracked to spawning locations. Subsequent observations of Floy-tagged or radio-tagged fish on the spawning grounds, allowed us to evaluate the spawn timing of hatchery and wild steelhead in the Twisp River (Figure 5.2). No significant differences in spawn timing were observed between hatchery and wild female steelhead from 2009 to 2016 (Goodman et al. 2017).

Figure 5.2. Mean spawn timing (day of year; center point) and 95\% CI (whiskers) of female steelhead by origin and year released upstream of the Twisp River weir based on PIT tag, Floy tag, or radio telemetry observations in $2009(\mathrm{H}=44 ; \mathrm{W}=17), 2010(\mathrm{H}=38 ; \mathrm{W}=24), 2011(\mathrm{H}$ = 27; W = 20), $2012(\mathrm{H}=8 ; \mathrm{W}=17), 2013(\mathrm{H}=5$; $\mathrm{W}=7), 2014(\mathrm{H}=8 ; \mathrm{W}=19), 2015(\mathrm{H}=$ 11; $\mathrm{W}=11$ ), and $2016(\mathrm{H}=2 ; \mathrm{W}=3)$.

## 5.5: Life History Monitoring

Monitoring the life history characteristics of hatchery summer steelhead adults occurs throughout their upstream migration to spawning grounds. Stock assessment sampling at Priest Rapids Dam, Wells Dam, the Twisp River weir, and PIT tag detection locations provide the data necessary to evaluate migration timing and straying, and contribute to the determination of survival rates and spawning ground demographics. Because steelhead carcasses are seldom recovered during spawning ground surveys, age and length at maturity information is derived primarily from adult fish sampled during hatchery broodstock spawning at Wells Dam. Age at maturity information is reported in section 5.1. Removal of adult hatchery steelhead in local sport fisheries is monitored through creel census and provides the information necessary to estimate harvest rates of hatchery fish and the effects of harvest on spawning ground demographics.

## Length at Maturity

Wild and hatchery-origin steelhead were sampled at Wells Dam to determine mean length by sex, saltwater-age, and fish origin, although some age and sex categories of wild fish were not represented in some years (Table 5.16). Hatchery-origin fish had similar or shorter mean fork lengths than wild fish for most age and origin comparisons within years and amongst all years examined (Table 5.16).

Table 5.16. Mean fork length (cm), number ( $N$ ), and standard deviation (SD) by sex, salt-age, and origin of steelhead sampled at Wells Dam by return year.

## Migration Timing

Evaluating the migration timing of hatchery and wild steelhead to Wells Dam is difficult because not all returning hatchery origin fish are adipose fin-clipped. Further, run monitoring is conducted concurrent with broodstock collection activities under protocols that limit the number of days, location (e.g., east or west ladders), and season (August through October) in which trapping occurs. Because of this we used observations of hatchery and wild steelhead PIT tagged at Priest Rapids Dam to evaluate migration timing to Wells Dam and into Methow River basin tributaries. To remove stray hatchery fish from the analysis, only hatchery fish marked with an adipose fin-clip (with or without a CWT), a snout CWT-only, and left- and right side yellow elastomer were included. For the 2006-2015 run years overall, wild fish arrived at Wells Dam an average of four days earlier than hatchery fish (Figure 5.3). Wild steelhead PIT tagged in 2015 had an earlier mean passage date (22 October) than hatchery steelhead (1 November) over the Lower Methow PIT array (LMR), but mean run-timing of hatchery and wild fish was similar at most other sites (Figure 5.4), regardless of salt-age at return (Figure 5.5).

Figure 5.3. Migration timing (mean +/- 95\% CI) by run year at Wells Dam of hatchery and wild steelhead PIT tagged and released from Priest Rapids Dam. Hatchery origin fish included those marked with an adipose fin-clip, an adipose fin-clip+CWT, a CWT-only, and left- or right-side yellow elastomer.

Figure 5.4. Mean (+/- 95\% CI) migration timing of hatchery and wild steelhead PIT tagged at Priest Rapids Dam in 2015. Hatchery origin fish included those marked with an adipose fin-clip, an adipose fin-clip+CWT, or a CWT-only. Detection locations include the Lower Methow River (LMR), and the Beaver, Gold, and Libby Creek (BGL) antenna arrays. The Upper Methow category includes the Lost River, Early Winters Creek, Wolf Creek, and the Methow River at Winthrop PIT tag arrays.

Figure 5.5. Mean (+/- 95\% CI) migration timing based on salt-age of hatchery and wild steelhead PIT tagged at Priest Rapids Dam in 2015. Detection locations include the Lower Methow River (LMR), and the Beaver, Gold, and Libby Creek (BGL) antenna arrays. The Upper Methow category includes the Lost River, Early Winters Creek, Wolf Creek, and Methow River at Winthrop PIT tag arrays.

## Contribution to Fisheries

Hatchery and wild steelhead returning to Wells Dam are removed for broodstock, may fallback below Wells Dam, or be removed in fisheries in the Columbia River upstream of Wells Dam before entering natal tributaries (Methow and Okanogan rivers). Sport fisheries in the Columbia River upstream of Wells Dam over the past 14 years have allowed the harvest of adipose finclipped hatchery origin steelhead, and have estimated the incidental take of wild steelhead through creel monitoring (e.g., WDFW 2016). Columbia River fisheries (including tribal harvest) have extracted about $7 \%$ of the hatchery steelhead and $2 \%$ of the wild steelhead upstream of Wells Dam on average (Table 5.17).

Table 5.17. Estimated tributary escapement of the hatchery and wild steelhead return to Wells Dam after broodstock removal, removal of fallback and double-counted fish based on PIT tag detections (escapement adjustments), and the impact of sport fisheries in the Columbia River.

| Brood | $\begin{gathered} \text { Run to Wells } \\ \text { Dam } \\ \hline \end{gathered}$ |  | Wells broodstock |  | Escapement adjustments |  | Columbia R. fisheries |  | Net tributary escapement |  |

Fisheries in tributaries upstream of Wells Dam are authorized when certain run composition and abundance measures have been met (see WDFW 2016). Under these criteria, sport fisheries targeting hatchery origin steelhead have been authorized in 13 of the last 15 years (Table 5.18). In addition to extraction in sport fisheries, some hatchery and wild fish were removed for broodstock to support local conservation hatchery programs or to reduce the proportion of hatchery origin fish ( pHOS ) on the spawning grounds. Tributary fisheries in the Methow and Okanogan river basins have removed about $21 \%$ of the estimated hatchery escapement and $2 \%$ of the wild escapement within the Methow and Okanogan tributaries between 2002 and 2016 (Table 5.18). Estimates of pHOS for the 2016 brood in both the Methow and Okanogan rivers were lower than the overall mean values for those rivers, due primarily to the relatively high return of wild fish.

Table 5.18. Estimated hatchery and wild steelhead escapement to the Methow and Okanogan river basins and the proportion of hatchery origin fish on the spawning grounds (pHOS) after local broodstock and fishery extraction. Tributary escapement was estimated utilizing radiotelemetry research (Attachment D), and accounts for 90.4\% of hatchery fish and $91.6 \%$ of wild fish reported in Table 5.15.

| Brood | Tributary escapement |  | Local broodstock |  | Tributary fisheries |  | Net escapement |  | pHOS |

## Straying

Determining stray rates of hatchery summer steelhead is difficult because adults are not recovered as carcasses on spawning grounds. We used PIT tag antenna arrays to evaluate the spawning distribution of 2012 and 2013 brood PIT tagged hatchery origin summer steelhead reared at Wells Hatchery and released into the Columbia, Methow, and Twisp rivers (Attachment D). Fish that entered tributaries on a date consistent with a spawning migration (March-May) and resided in the tributary for a period when spawning was on-going, were considered to have spawned in the tributary. Hatchery fish that met these criteria within a tributary other than their tributary of release were considered to have strayed. Based on completed adult return data from the 2012 brood, stray rates for Methow Basin steelhead releases (Methow and Twisp) averaged 9.5\% (Table 5.19). These estimates should be considered preliminary values because efficiency of the antenna arrays are highly variable between sites, and PIT tag detections were very low for some release groups (e.g., 2012 Columbia River releases).

Table 5.19. Detection of adult hatchery summer steelhead released from Wells Hatchery into Methow Basin tributaries. Adult returns were detected in the Twisp River (TWR), Chewuch River (CRW), Methow River (MRW, GLC [Gold Creek], EWC [Early Winters Creek], and LOR [Lost River]) antenna arrays and at Zosel Dam in the Okanogan River basin. Detections of 2013 brood releases are considered incomplete because they include only 1-salt returns.

|  | Release river (donor pop.) | Recipient river, river area, or tributary |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

${ }^{\text {a }}$ Includes one return to Wells tailrace.

## Smolt to Adult Survival and HRR

The smolt-to-adult return of summer steelhead was calculated from run evaluation monitoring conducted at Wells Dam and broodstock sampling conducted at Wells Hatchery. The HRR is
calculated as the number of hatchery adult returns divided by the number of adult broodstock used to produce the return cohort. The HRR for the most recent brood where complete adult return data were available (2012 brood) was 13.4 for Wells Hatchery releases, and 24.2 for Twisp River conservation program releases (Table 5.20). These values were below the HRR target of 19.6 for Wells releases but above the target value for Twisp River releases.

Table 5.20. Number of broodstock spawned (including pre-spawn mortalities) and smolts released by brood year from Wells Complex hatchery facilities, including the Twisp conservation program (T). Adult returns from Winthrop National Fish Hatchery and Cassimer Bar Hatchery were indistinguishable from Wells Hatchery releases for the 1996-2006 broods and are thus included in all categories for those years.

| Brood <br> year | Number of <br> broodstock | Smolts <br> released | Adult <br> returns | SAR (\%) | \# Smolts/ <br> adult | HRR |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Natural Replacement Rates

The natural replacement rate (NRR) of wild summer steelhead in the Methow River basin was calculated as the number of natural origin recruits divided by the overall spawning population of hatchery and natural origin adults of the parent brood (Attachment D). The NRR of the last brood for which complete adult return data was available (2010 brood) was 0.245 (Table 5.21), which is slightly lower than the mean NRR of the 1996-2010 broods (0.294).

Table 5.21. Natural replacement rate (NRR) of Methow River basin steelhead spawners. The NRR is calculated by dividing the number of natural origin return (NOR) recruits produced by the sum of the spawning population of hatchery origin (HOR) and natural origin (NOR) spawners.

| Parent brood year | Methow Basin run escapement (parent brood) |  |  | Methow Basin recruits |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | HOR | NOR | Total | NOR | NRR |
| 1996 | 363 | 66 | 429 | 319 | 0.744 |
| 1997 | 1,787 | 185 | 1,972 | 715 | 0.363 |
| 1998 | 2,264 | 77 | 2,341 | 745 | 0.318 |

## Proportionate Natural Influence

The Hatchery Scientific Review Group (HSRG) developed guidelines for salmon and steelhead hatchery programs intended to provide a foundation of hatchery reform principals that should aid hatcheries in the Pacific Northwest in meeting conservation and sustainable harvest goals (HSRG 2008). These guidelines provide a means of assessing the genetic risk of hatchery programs to
natural populations by calculating the proportionate natural influence (PNI) of a population. The PNI is calculated as: (the proportion of natural origin fish within the broodstock [pNOB] $) /(\mathrm{pHOS}+\mathrm{pNOB})$. A PNI value $>0.5$ indicates that genetic selection pressures from the natural environment have a stronger influence on the population than those from the hatchery environment, and a PNI $\geq 0.67$ was recommended for conservation programs (HSRG 2009). For the 2002-2016 broods, PNI has been slightly higher in the Methow Basin than in the Okanogan Basin, but mean values for both basins are low and indicate that most genetic selection pressure on the populations comes from the hatchery environment (Table 5.22).

Table 5.22. The proportionate natural influence (PNI) calculated for specific broods of spawning steelhead in the Methow and Okanogan river basins. The proportion of hatchery origin spawners (pHOS) in the escapement of each tributary was derived from Table 5.16. The net proportion of natural origin fish within each brood (pNOB) was estimated as the sum of the proportion of each salt-age of hatchery origin spawners (HOS) multiplied by the pNOB for that salt age. The PNI was calculated as: $\mathrm{pNOB} /(\mathrm{pNOB}+\mathrm{pHOS})$.

| Brood | Net tributary escapement |  | HOS age proportion |  | pNOB |  | $\begin{gathered} \text { Net } \\ \text { pNOB } \end{gathered}$ | PNI |

Subject: 2016 Twisp and Methow River Smolt Estimates.

Smolt trapping in the Methow River basin was conducted to estimate the number of emigrating spring Chinook salmon (Oncorhynchus tshawytscha) and steelhead (O. mykiss) from the Twisp and Methow Rivers. This information should assist in estimating the freshwater productivity and survival of target stocks and provide the productivity indicator information necessary to evaluate Objective 2 of the M\&E Plan adopted by the Wells HCP Hatchery Committee (Hillman et al. 2013):

Objective 2: Determine if the proportion of hatchery fish on the spawning grounds affects the freshwater productivity of supplemented stocks.

## Methods

Rotary smolt traps of different sizes were operated in several configurations depending on the specific requirements of each site. The Twisp River trap is located at approximately rkm 2 and used a single trap with a 1.5 m cone diameter because of low stream flow and a relatively narrow stream channel. The Methow River trap is located at approximately rkm 30 and used traps with cone diameters of 2.4 m and 1.5 m to increase trap efficiency over a greater range of river discharge. Large variation in discharge in the Methow River also required the use of two trapping positions due to the channel configuration and safety of personnel and fish. A 1.5 m trap was deployed in the lower position at the Methow site at discharges below $45.3 \mathrm{~m}^{3} / \mathrm{s}$. At discharges greater than $45.3 \mathrm{~m}^{3} / \mathrm{s}$, an additional 2.4 m trap was installed and operated in tandem with the 1.5 m trap. The tandem traps were operated approximately 30 m upstream of the low position (i.e., upper position).

The Twisp trap was operated continuously during all hours of the day if debris and river discharge allowed. Trapping occurred only during nighttime hours at the Methow site. Trap cones were lowered 1-2 hours before sunset and raised 1-2 hours after sunrise. The traps were also pulled to the bank during the day to avoid debris as well as to allow easier access for boaters and recreational users as stated in our Okanogan County Conditional Use Permit. During
periods of minimal catch, fish were removed from the traps each morning. During periods of greater discharge and/or fish abundance, traps were monitored throughout the night to minimize mortality of captured fish and avoid equipment damage from debris. Debris was removed from the catch box by a small rotating drum-screen powered directly by the rotation of the cone (2.4m trap) or by the cone contacting a rubber tire that caused the drum-screen to rotate ( $1.5-\mathrm{m}$ traps). Traps were either connected to a main cable spanning the river (Methow River site), or to a single point on the right bank (Twisp River site).

## Biological Sampling

Captured fish were retained in a $0.37 \mathrm{~m}^{3}$ live box and were sorted, counted by species, and classified as hatchery or wild origin at each trap. Fish utilized for mark/recapture trials or tagged with passive integrated transponder (PIT) tags were held in $0.11 \mathrm{~m}^{3}$ or $1.0 \mathrm{~m}^{3}$ auxiliary live boxes affixed to the rear section of each trap. Salmonids were anesthetized in a solution of MS222 prior to sampling and allowed to recover prior to release. Salmonids were visually classified as fry, parr, transitional, or smolt. Fry were defined as newly emerged fish without a visible yolk sac and largely underdeveloped pigmentation, with a fork length less than 50 mm . Parr had a fork length equal to or greater than 50 mm and distinct parr marks on their sides. Transitional migrants had faded parr marks, bright silver coloration, and some scale loss. Salmonids lacking or having highly faded parr marks, bright silver color, and deciduous scales were classified as smolts.

Hatchery origin fish were identified by the presence of marks (i.e., adipose fin-clip, ventral finclip), tags (i.e., coded-wire tags [CWT], PIT tags, elastomer tags), or by eroded fins or scale samples if no other marks or tags were identified. Juvenile salmonids lacking any marks, tags, or fin erosion were considered wild.

Sampling protocols differed by origin and species, although all fish were scanned for PIT tags prior to release. Hatchery-origin fish were counted by mark type, while most wild-origin fish were counted, measured to the nearest millimeter, and weighed to the nearest 0.1 g . Scale samples were collected from the majority of wild summer steelhead captured throughout the migration period. Scale samples were analyzed by the WDFW Scale Lab to estimate the contribution of different age classes to the migrating population. Most wild spring Chinook salmon and steelhead were PIT tagged prior to release, and all PIT tagging information was uploaded to a regional PIT tag database (PTAGIS) maintained by the Pacific States Marine Fisheries Commission. Non-salmonids were counted by species or by family if they were too small to identify to species (e.g., Catostomidae).

Age, trap location, and DNA analysis was used to determine race (spring or summer) of captured juvenile Chinook salmon. All Chinook salmon captured in the Twisp River trap were considered spring Chinook, regardless of size because summer Chinook have not been documented spawning upstream of the trap. All yearling (i.e., age-1) Chinook captured at the Methow River trap during the spring migration period were considered spring Chinook because spring Chinook are yearling migrants and summer Chinook are typically subyearling migrants. All age-0 Chinook salmon fry and parr captured at the Methow River trap during spring were considered summer Chinook.

During periods when the trap was not operating (e.g., mechanical problems, high debris, or high discharge) the number of spring Chinook, summer Chinook, and summer steelhead captured was estimated. The estimated daily number of fish that would have been captured had the trap been fishing was calculated using the average number of fish captured two days prior to the day being estimated and two days after redeployment of the trap. During extended non-trapping periods at the Twisp site, we estimated emigration using the Twisp PIT tag antenna array (PTAGIS code TWR) by expanding run-of-the-river PIT tag detections at the site by the estimated tag rate determined from smolt trap captures, and the estimated antenna array efficiency based on discharge/detection efficiency modeling as conducted for the smolt traps.

## Population Estimates

Groups of at least 50 juvenile salmonids were used for trap efficiency trials whenever possible. However, low abundance of target species and low trap efficiency, resulting in low number of captured individuals, required the use of some groups with fewer than 50 fish. Mark/recapture fish were marked using a top or bottom caudal fin-clip, PIT tag, or were stained with Bismarck brown dye. Fish used in trap efficiency trials were anesthetized prior to marking and then held in an auxiliary live box for up to three days until the day of the trial. Marked fish were transported upstream of the trap in a $1,211 \mathrm{~L}$ two-chamber transport tank, or 18.9 L snap-lid buckets. Fish were divided into two equal groups and released on both stream banks to increase the likelihood that marked fish were uniformly mixed with unmarked fish and therefore representative of the population when recaptured. Releases of marked fish occurred in the evening after the trap was set. Marked fish from the Methow River trap were transported and released approximately 5.6 km upstream of the trap (rkm 36). Fish marked for Twisp River trap mark groups were transported and released approximately 5.8 km upstream of the trap (rkm 8). Recaptured fish were recorded by mark type, measured, and released. Marked groups of fish were released over the greatest range of discharge possible in order to best represent the range of flows in the trap efficiency-flow regression model used to estimate the daily trap efficiency. The mean daily discharge for each trapping period was calculated based on the start and end time of trap operation. Discharge was measured and recorded every 15 min at USGS gauging station No. 12449950 (Methow River near Pateros, Washington) and station No. 12448998 (Twisp River near Twisp, Washington).

Emigration estimates were calculated using estimated daily trap efficiency, which was derived from a weighted regression formula using trap efficiency (dependent variable) and discharge (independent variable). Trap efficiency was calculated using the following formula:

Trap efficiency $=E_{i}=R_{i}+1 / M_{i}$
Where $E_{i}$ is the trap efficiency during time period $i ; M_{i}$ is the number of marked fish released during time period $i$; and $R_{i}$ is the number of marked fish recaptured during time period $i$. The number of fish captured was expanded by the estimated daily trap efficiency $(e)$ to estimate the daily number of fish migrating past the trap $\left(N_{i}\right)$ using the following formula:

Estimated daily migration $=\hat{N}_{i}=\frac{\left(C_{i}+1\right)}{\hat{e}_{i}}$

Where $N_{i}$ is the estimated number of fish passing the trap during time period $i$; $C_{i}$ is the number of unmarked fish captured during time period $i$; and $e_{i}$ is the estimated trap efficiency for time period $i$ based on the regression equation.

The variance for the total daily number of fish migrating past the trap was calculated using the following formula:
Variance of daily migration estimate $=$

$$
\begin{aligned}
\operatorname{Var}\left(\sum_{i=1}^{n} \hat{N}_{i}\right)= & \sum_{i} \hat{N}_{i}^{2}\left(\frac{N_{i} \hat{e}_{i}\left(1-\hat{e}_{i}\right)}{\left(C_{i}+1\right)^{2}}+\frac{4\left(1-\hat{e}_{i}\right)}{\hat{e}_{i}} M \hat{S} E\left(1+\frac{1}{n}+\frac{\left(x_{i}-\bar{x}\right)^{2}}{(n-1) s_{x}^{2}}\right)\right)+ \\
& \sum_{i} \sum_{j} 4\left(\hat{N}_{i}\left(1-\hat{e}_{i}\right)\right)\left(\hat{N}_{j}\left(1-\hat{e}_{j}\right)\right) \cdot\left[\hat{\operatorname{Var}}\left(b_{0}\right)+x_{i} x_{j} \hat{\operatorname{Var}}\left(b_{1}\right)\right]
\end{aligned}
$$

Where $x_{i}$ is the discharge for time period $i$, and $n$ is the sample size (number of mark/recapture trials used in model). If a relationship between discharge and trap efficiency was not present (i.e., $P<0.05 ; r^{2} \approx 0.5$ ), pooled trap efficiency was used to estimate daily emigration:

Pooled trap efficiency $=E_{p}=\frac{\sum_{k=1}^{n} r_{k}}{\sum_{k=1}^{n} m_{k}}$

Where $\sum_{k=1}^{n} m_{k}=$ the total number of marked fish for all $k$ mark/recapture events;

$$
\sum_{k=1}^{n} r_{k}=\text { the total number of marked fish that were recaptured from all } k \text { mark/recapture }
$$ events.

The daily emigration estimate was calculated using the formula:

Daily emigration estimate $=\hat{N}_{i}=C_{i} / E_{p}$

The variance for daily emigration estimates using the pooled trap efficiency was calculated using the formula:

Variance for daily emigration estimate $=\operatorname{var}\left[\hat{N}_{i}\right]=\hat{N}_{i}^{2} \frac{E_{p}\left(1-E_{p}\right) / \sum M}{E_{p}^{2}}$

The total emigration estimate and confidence interval were calculated using the following formulas:

Total emigration estimate $=\sum \hat{N}_{i}$
$95 \%$ confidence interval $=1.96 \times \sqrt{\sum \operatorname{var}\left[\hat{N}_{i}\right]}$

A valid estimate would require the following assumptions to be true concerning the trap efficiency trials:

1. All marked fish passed the trap or were recaptured during time period $i$.
2. The probability of capturing a marked or unmarked fish is equal.
3. Marked individuals were randomly dispersed in the population before recapture.
4. All marked fish recaptured were identified.
5. Marks were not lost between the time of release and recapture.

Ideally, a species-specific discharge/capture efficiency model (i.e., flow model) was developed at each trap site within each year for each trap position used. When this was not possible, we used the following protocols in order of priority to determine the methodology used to develop production estimates for each trap site and species:

1. Flow model using target species within current year.
2. Flow model using target species over multiple years.
3. Flow model using target and surrogate species within current year.
4. Flow model using target and surrogate species over multiple years.
5. Flow model using surrogate species within current year.
6. Flow model using surrogate species over multiple years.
7. Pooled efficiency estimate using target species within current year.
8. Pooled efficiency estimate from previous year.

## Juveniles Per Redd

Production estimates for each cohort age class, by trapping location, were summed to produce a total brood year emigration estimate. For spring Chinook, the estimate of fall-migrant parr was added to the estimate of yearling emigrants the following spring to produce a total emigrant estimate for each brood year. Additionally, to estimate over-winter emigration the daily number of PIT tagged juvenile Chinook detected at the Twisp River PIT tag array was expanded by a tag rate estimated from smolt trap captures of yearling Chinook captured during the entire migration period. This estimate was expanded by the estimated daily detection efficiency based on flow at the PIT tag array. The flow/efficiency relationship of the PIT tag array was determined through mark/recapture efficiency trials conducted at different flows with PIT tagged fish released above the array and detected at sites downstream of the PIT array (e.g., Rocky Reach Dam). The resulting over-winter emigration estimate was added to the juvenile production estimate from trap captures. Spring Chinook fry that emigrate during the spring past the Twisp and Methow
smolt traps are not included in production estimates at those sites, thus their contribution to overall juvenile production is unknown.

The steelhead emigration estimate at each trap location was multiplied by the proportion of migrants from each brood determined through scale pattern analysis. Because juvenile steelhead potentially emigrate at age-4 or later, determining the total number of emigrants produced from one brood of spawning adults requires at least four years of emigration estimates. The number of emigrants per redd for each brood year was calculated by dividing the total brood year emigrant production estimate by the total number of redds located above the trap in that brood year estimated through spawning ground surveys.

For spring Chinook salmon, egg deposition values used to calculate egg-to-emigrant survival were derived from carcass surveys and hatchery broodstock sampling. For each brood examined, the number of eggs deposited was estimated using the proportions by age and origin of the female spawning population within each basin as determined through spawning ground surveys. Each redd was then multiplied by the mean fecundity values by age and origin determined through sampling of Methow Hatchery broodstock, and adjusted by the mean percent of eggs retained in the body cavity determined through spawning ground (carcass) surveys. For summer steelhead, egg deposition values were derived by multiplying the total number of redds in each basin by mean fecundity values according to age and origin of the female steelhead population as determined through run composition and hatchery broodstock sampling at Wells Hatchery.

Spawning ground surveys identified summer steelhead and spring Chinook redds downstream of the Methow and Twisp rivers trap sites in some years. It was assumed that redds located downstream from each trap site did not contribute to production estimates calculated at upstream smolt traps. To calculate total production and emigration estimates for the populations, the egg-to-emigrant survival rates calculated for redds upstream of the trap were applied to the estimated number of eggs deposited downstream of the trap. Confidence intervals (95\%) were adjusted in a similar manner. Total brood year emigration estimates were calculated by adding the estimated number of emigrants produced downstream of the trap to the estimate of emigrants produced upstream of the trap location.

## Results

## Smolt Trap Operation

Trapping in the Methow River basin in 2016 began at the Methow River site on 19 February and at the Twisp River site on 27 February. Trapping at both locations was interrupted over the course of the trapping season due to high river discharge. Trapping at the Methow site was interrupted on two occasions for a total of 17 days between 19 February and 5 December. Trapping at the Twisp site was interrupted on three occasions for a total of 35 days between 27 February and 5 December. River discharge peaked earlier in the spring than average. River discharge at both trapping locations were above the historical daily values for all but four days during the month of April. The early peak was followed by below average discharge for the majority of the late spring period from late-May through July (Figures 1 and 2). Near or above
average discharge during the summer and fall months allowed fairly consistent trap operation until ice accumulation in early December.

Figure 1. Methow River 2016 daily discharge and 57-year mean as measured at the USGS gauging station No. 12449950 (Methow River near Pateros, Washington).

Figure 2. Twisp River 2016 daily discharge and 31-year mean as measured at the USGS gauging station No. 12448998 (Twisp River near Twisp, Washington).

## Daily Captures and Biological Sampling

## 2014 Brood Chinook Salmon

A total of 487 wild yearling Chinook salmon emigrants were captured at the Methow site between 19 February and 30 June, with the peak capture ( $N=56$ ) occurring on 1 April (Figure 3). We inserted PIT tags into 476 of the wild smolts captured, and subsequently released 471 after subtracting three mortalities and two shed tags (Appendix A). Overall mortality of wild yearling Chinook totaled three of the 487 fish captured (0.62\%). Instead of PIT tagging hatchery fish, we utilized 65 hatchery spring Chinook salmon that had existing PIT tags to facilitate trap efficiency mark/recapture trials. In addition to the tagged fish, 743 hatchery Chinook were marked with a caudal fin clip and released upstream to aid in efficiency trials. Overall mortality of hatchery Chinook at the Methow site totaled 74 out of 3,339 fish captured (2.2\%). Hatchery smolts had a significantly greater mean fork length ( 128.6 mm ) than wild Chinook smolts ( 99.1 mm ) captured at the Methow trap (Mann-Whitney U-test: $P<0.001$; Table 2).

The Twisp River trap captured 403 wild yearling spring Chinook salmon smolts between 27 February and 30 June. Peak capture occurred on 2 April ( $N=36$; Figure 4). We inserted PIT tags into 397 of the captured wild fish and all were subsequently released (Appendix A). Three of the 403 yearling Chinook captured had existing PIT tags when captured, and three additional fish were in poor condition when captured and were not tagged prior to release. Overall mortality of wild yearling Chinook at the Twisp site totaled one of the 403 fish captured ( $0.25 \%$ ). In addition to the 300 hatchery spring Chinook that were caudal clipped, we used 301 hatchery spring Chinook that had existing PIT tags for mark/recapture trials. There was no mortality experienced by any of the 2,177 hatchery Chinook salmon smolts captured at the Twisp trap.

Figure 3. Daily capture of wild Chinook salmon smolts (YCW) at the Methow River smolt trap in 2016.

Figure 4. Daily capture of wild spring Chinook salmon smolts (YCW) at the Twisp River smolt trap in 2016.

## 2015 Brood Chinook Salmon

Subyearling Chinook salmon fry $(N=4,581)$ and parr $(N=1,931)$ captured at the Methow trap between 19 February and 30 September had mean fork lengths of 40.6 mm and 65.3 mm , respectively (Table 2). Mortality during this period totaled 97 fry ( $2.1 \%$ ) and 12 parr ( $0.62 \%$ ). An additional 179 emigrant Chinook parr were captured during the fall trapping period between 1 October and 5 December. The mean fork length of Chinook parr during this period was 95.6 mm (Table 2), and peak captures occurred on 22 October ( $N=15$ ). We inserted PIT tags into 174 of the Chinook parr captured and 173 were released after a single mortality occurred prior to being released ( $0.57 \%$; Appendix A). Six of the parr captured had existing PIT tags from upstream sources. Tissue samples were collected from 174 of the fall-captured parr, and genetic analysis was conducted on 100 of those samples. One of the samples failed to produce a genotype and was excluded from analysis. Of the remaining 99 samples, analysis indicated that 96 ( $97.0 \%$ ) of the sampled parr were spring Chinook, and three (3.0\%) were summer Chinook (Appendix B). These results are similar to results from sampling of fall parr in previous years (Table 1).

The Twisp trap captured 1,277 subyearling spring Chinook salmon between 27 February and 5 December, and peak captures occurred on 21 October ( $N=84$; Figure 5). We inserted PIT tags into 612 Chinook parr and 611 were released with tags after one fish shed a tag (Appendix A). There were also five Chinook parr that had existing PIT tags at capture. Overall, four subyearling Chinook mortalities occurred ( $0.31 \%$ ). Fall migrant parr had a mean fork length of 88.6 mm (Table 2).

Figure 5. Daily capture of subyearling wild spring Chinook salmon (Feb - Sep) and migrant parr (Oct-Dec) at the Twisp River smolt trap in 2016.

Table 1. Percent of fish that were assigned to the spring Chinook salmon race from DNA analysis conducted on juvenile Chinook salmon captured at the Methow River smolt trap by trapping year and trapping period. During the spring period, samples in 2007 and 2008 were collected from age- 1 yearling smolts, but samples from other years were collected from age-0
parr.

| Trapping year | Spring (start-30 Jun) | Summer (1 Jul-30 Sep) | Fall (1 Oct-end) |
| :---: | :---: | :---: | :---: |

## Summer Steelhead

The Methow River trap captured 190 wild summer steelhead emigrants (smolt and transitional) between 19 February and 30 June, with peak capture on 2 April ( $N=26$; Figure 6). We inserted PIT tags into 179 wild steelhead emigrants and all survived to release (Appendix A). Nine additional fish had existing PIT tags when captured; one fish originally tagged in 2014, seven fish tagged in 2015, and one fish tagged at the Twisp trap in 2016. In addition to these, one fish was in poor condition when captured and was not tagged prior to release. Overall mortality of emigrant steelhead totaled one of the 190 fish captured ( $0.53 \%$ ). Most wild summer steelhead migrants were age-2 fish (64.7\%), which had a mean fork length of 174.2 mm (Table 3). A total of 473 hatchery steelhead juveniles were captured at the Methow River trap. There were no mortalities of hatchery summer steelhead at the Methow trap site.

The Methow River trap captured 23 wild summer steelhead fry and 112 wild parr between 19 February and 5 December. Steelhead parr greater than 65 mm and in good physical condition were PIT tagged $(N=104)$, and 103 were released after subtracting a single mortality (Appendix A). Overall mortality of fry $(N=1)$ and parr $(N=1)$ totaled $(1.5 \%)$ of the total fry and parr captured. Wild steelhead parr and fry had mean fork lengths of 108.1 mm and 29.7 mm respectively.

Figure 6. Daily capture of wild steelhead smolt and transitional migrants at the Methow River smolt trap in 2016.

Table 3. Mean length, weight and condition factor by age class of wild transitional and smolt summer steelhead emigrants captured in Methow Basin smolt traps in 2016.

| Age | $N(\%)$ | Fork (mm) |  |  | Weight (g) |  |  | Mean <br> K-factor |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| Methow River trap |  |  |  |  |  |  |  |  |
| 1 | 35 (20.6) | 141.1 | 35 | 12.6 | 29.9 | 35 | 7.9 | 1.0 |
| 2 | 110 (64.7) | 174.2 | 110 | 24.8 | 55.1 | 110 | 23.7 | 1.0 |
| 3 | 24 (14.1) | 185.7 | 24 | 23.8 | 64.1 | 24 | 24.6 | 1.0 |
| 4 | 1 (0.6) | 198.0 | 1 | -- | 67.5 | 1 | -- | 0.9 |
| Twisp River trap |  |  |  |  |  |  |  |  |
| 1 | 11 (7.7) | 134.2 | 11 | 15.2 | 27.4 | 11 | 8.6 | 1.1 |
| 2 | 105 (73.4) | 157.0 | 105 | 15.4 | 39.6 | 105 | 12.2 | 1.0 |
| 3 | 26 (18.2) | 178.3 | 26 | 18.6 | 57.5 | 26 | 15.5 | 1.0 |
| 4 | 1 (0.7) | 165.0 | 1 | -- | 44.1 | 1 | -- | 1.0 |

A total of 160 wild summer steelhead emigrants (smolt and transitional) were captured at the Twisp trap between 27 February and 30 June, and the peak capture occurred on 2 April ( $N=21$; Figure 7). Wild emigrants (all ages combined) had a mean fork length of 159.4 mm , and were primarily age-2 fish (73.4\%; Table 3). We inserted PIT tags into 139 wild steelhead emigrants and all were released alive (Appendix A). Twenty additional fish had existing PIT tags when captured; 17 of these were originally tagged in 2015, and three were originally tagged in 2014. There was only a single trapping mortality experienced by smolt or transitional steelhead out of the 160 captured at the Twisp site ( $0.63 \%$ ). A total of 2,100 hatchery summer steelhead juveniles were captured at the Twisp river trap, and no mortalities were experienced ( $0.0 \%$ ). We conducted upstream releases of 417 hatchery steelhead for mark/efficiency trials, of which 113 had existing PIT tags, and 301 received caudal clips for identification.

Non-migrant summer steelhead captured at the Twisp trap included 51 wild fry and 276 wild parr captured between 27 February and 5 December (Figure 8). We inserted PIT tags into 242 steelhead parr greater than 65 mm and all survived until release (Appendix A). Overall mortality of fry $(N=0)$ and parr $(N=1)$ represented $0.31 \%$ of the total fry and parr captured $(N=327)$. Wild steelhead parr and fry had mean fork lengths of 102.7 mm and 35.8 mm respectively.

## Population Estimates

## 2014 Brood Spring Chinook Salmon

Mark/recapture efficiency trials for estimating wild spring Chinook salmon smolt production should ideally be conducted with wild Chinook salmon. Due to the low capture numbers for wild fish at the Methow trap, many efficiency trials utilize hatchery Chinook as surrogates. We did not conduct any mark/recapture trials for the low trap position because higher than average
river discharge required operation in the upper position for most of the spring trapping season. A significant relationship did exist ( $P<0.01 ; \mathrm{r}^{2}=0.52$; Table 5) from trials conducted during previous seasons, and the regression ( $y=-2.57 \mathrm{E}-05 x+0.161723324$ ) was used for the low trapping position in 2016. For the upper trapping position, a mark/recapture trial was conducted with wild spring Chinook as well as two trials using hatchery Chinook. These three groups were combined with releases conducted during the previous four years, which resulted in a significant relationship ( $P<0.01, \mathrm{r}^{2}=0.75$; Table 5) and the regression ( $y=-2.52 \mathrm{E}-05 x+0.270693602$ ) was used for the upper position in 2016. Using both these flow models, the estimated number of yearling spring Chinook salmon emigrants was 35,330 ( $\pm 5,169$, $95 \%$ CI). Combining the yearling emigrants with the estimate of parr that emigrated past the trap in the fall of 2015 (34,402 $\pm 180,061,95 \%$ CI), a total estimated 69,732 ( $\pm 180,135,95 \%$ CI) 2014 brood wild spring Chinook migrated from the Methow River basin between 1 October 2015 and 30 June 2016. Emigration peaked during November 2015 when $49.3 \%$ of the estimated emigrants migrated past the Methow trap (Figure 9).

Two mark/recapture trials were conducted with hatchery spring Chinook smolts at the Twisp trap in the spring of 2016, but they were conducted at flows that were much higher than any previous releases, and they could not be combined with historical groups to produce a significant relationship. However, a significant efficiency discharge relationship existed from release groups conducted during previous seasons ( $P<0.01, \mathrm{r}^{2}=0.64$; Table 6). The flow model regression $(y=-0.00056877 x+0.529960351)$ was used to estimate that $6,519( \pm 1,561,95 \%$ CI) smolts emigrated past the Twisp River trap between 27 February and 30 June 2016. There was one redd identified downstream of the Twisp trap in 2014, so an estimated 48 migrants were added to produce a total of $6,567( \pm 1,566,95 \%$ CI) yearling emigrants from the Twisp River in 2016. Snow et al. (2016) estimated that 18,290 ( $\pm 4,747,95 \%$ CI) 2014 brood spring Chinook salmon parr emigrated from the Twisp River in the fall of 2015, which included 133 expected emigrants produced from a single redd found downstream of the Twisp trap in 2014. In addition to the smolt trap estimates, mark/detection trials performed at the Twisp PIT tag array (Table 7) were used to estimate that 3,443 ( $\pm 1,272,95 \% \mathrm{CI}$ ) spring Chinook emigrated between 21 November 2015 and 26 February 2016 when the smolt trap was not operating. An additional 25 over-winter migrants were estimated from the single redd located downstream of PIT array in 2014 to total 3,468 ( $\pm 1,276,95 \%$ CI) over-winter migrants. Adding all emigrant totals, the complete emigration estimate for the 2014 spring Chinook brood was 28,325 ( $\pm 5,167,95 \%$ CI) fish. Emigration peaked during November 2015, when $50.8 \%$ of the 2014 brood migrated from the Twisp River (Figure 10).

To corroborate the Chinook estimates calculated from the Twisp River screw trap, we created an estimate from expanding PIT interrogations at the TWR PIT array. We found the 2014 brood Chinook captured between 1 July 2015 and 30 June 2016 to have an existing PIT tag rate of 2.35 percent. The PIT tag rate in conjunction with the flow/efficiency regression created for the TWR PIT antennas ( $y=-0.00174870 x+1.336948968$; Table 7) was used to estimate that 27,574 ( $\pm$ $7,151,95 \%$ CI) 2014 brood spring Chinook migrated past the TWR interrogation site. An additional 202 emigrants were added to account for the one redd located downstream of the TWR site to estimate a total of 27,776 ( $\pm 7,177,95 \%$ CI) 2014 brood spring Chinook migrating from the Twisp River between 1 July 2015 and 30 June 2016. This estimate accounts for 98.1 \% of the estimate created using the screw trap method. There are slight discrepancies between the
screw trap and the PIT array estimates within the given trapping periods (Figure 11). The PIT array method estimated more sub-yearling migrants, but less yearling emigrants than the screw trap. For consistency, all production tables include the population estimates created from the screw trap estimation method.

## 2015 Brood Spring Chinook Salmon

Sufficient numbers of fish could not be obtained at the Methow trap site to develop a flow regression model for the low position in the fall of 2016, and a pooled efficiency was used to estimate fish passage during this time period (Table 8). There were 168 marked Chinook parr released above the trap in the fall of 2016, and five were recaptured providing a pooled trap efficiency of approximately $2.98 \%$. Using this pooled efficiency, an estimated $5,847( \pm 16,007$, $95 \%$ CI) subyearling spring Chinook migrated past the trap in the fall of 2016.

A single mark/recapture trial was conducted at the Twisp trap site in the fall of 2016. Combining this group with trials conducted in 2014 and 2015 showed that trap efficiency was significantly related to discharge ( $P<0.01, \mathrm{r}^{2}=0.57$; Table 9 ), and the flow model regression ( $y=$ $0.000908708 x+0.119169681$ ) was used to estimate that $13,831( \pm 3,198,95 \%$ CI) 2015 brood spring Chinook salmon parr emigrated past the Twisp trap between 1 July and 5 December 2016. The trap operated for the entire fall period, so adding estimated migrants using the Twisp PIT tag array was not needed in the fall of 2016. In addition, there were no Chinook redds observed below the Twisp trap site in 2015, so no expansion to account for migrants originating from downstream of the trap was necessary.

Table 7. Mark/detection efficiency trials used to estimate emigration of spring Chinook salmon over the Twisp River PIT tag array (TWR) during non-trapping periods.

## Summer Steelhead

Due to low capture numbers of migratory steelhead, no mark/recapture trials were conducted with steelhead in 2016 at the Methow trap. No significant regression model exists for steelhead at the Methow River trap, so the yearling Chinook flow/efficiency models were used to estimate steelhead production for each position (see Table 5). Combining numbers from both trapping positions, an estimated 16,943 ( $\pm 4,393,95 \%$ CI) summer steelhead emigrated past the Methow River trap in 2016. An additional 696 migrants were estimated from redds located downstream of the trap in 2012 through 2015, which provides a total estimated migration of $17,639( \pm 4,482$, $95 \%$ CI) summer steelhead from the Methow River basin in 2016. Most 2016 migrants were age-2 fish (65.6\%) from the 2014 brood (Table 10). The entire 2012 brood migration was estimated to be 25,726 ( $\pm 4,629,95 \%$ CI) fish, including 392 migrants that were expected from redds $(N=9)$ located downstream of the Methow trap in 2012 (Table 14).

Numerous mark/recapture trials were conducted with wild summer steelhead at the Twisp site in 2016, but none contained more than 35 fish. A flow efficiency relationship from previous years’ release groups was used to estimate steelhead emigration at the Twisp site in 2016 (Table 11). The flow model regression ( $y=-0.00029758 x+0.410040455 ; ~ P<0.01, \mathrm{r}^{2}=0.52$ ) was used to estimate that $5,132( \pm 1,733,95 \% \mathrm{CI})$ wild summer steelhead migrated past the Twisp River trap between 27 February and 30 June 2016. An additional 594 migrants were estimated from redds located downstream of the trap in 2012 through 2015, which provides a total estimated migration of $5,726( \pm 1,831,95 \%$ CI) summer steelhead from the Twisp River in 2016. Most 2016 migrants were age-2 fish (74.6\%) from the 2014 brood (Table 10). Combining numbers from the last four years, the entire 2012 brood migration was estimated to be 5,882 ( $\pm 1,514,95 \% \mathrm{CI})$ fish, which included 446 expected migrants produced from redds $(N=10)$ downstream of the Twisp trap in 2012 (Table 14).

## 2015 Brood Summer Chinook Salmon

Four mark/recapture trials were conducted at the Methow trap with subyearling Chinook for the low position in the spring of 2016, but no significant relationship was found between flow and efficiency. We therefore used a pooled efficiency of approximately 0.25 percent to estimate Chinook emigration during that period (Table 12). Three mark/recapture trails were conducted with subyearling Chinook for the upper trapping position in 2016. These groups, combined with trials from previous seasons, were used to create a flow efficiency model to estimate emigrants during the upper trapping period (Table 12). The flow model regression ( $y=-0.000029349949 x$ $+0.2529416 ; P<0.01, \mathrm{r}^{2}=0.80$ ), was used in addition to the pooled efficiency to estimate that 761,769 ( $\pm 4,082,084,95 \%$ CI) wild summer Chinook migrated past the Methow trap in 2016. There were 462 summer Chinook redds located downstream of the Methow trap in 2015, so an estimated 457,656 ( $\pm 3,164,02495 \% \mathrm{CI}$ ) fish migrated from redds located below the trap, thus bringing the total to $1,219,425( \pm 5,164,732,95 \% \mathrm{CI})$ wild 2015 brood summer Chinook migrants from the Methow River in 2016.

## 2014 Brood Coho Salmon

A total of 129 wild juvenile Coho migrants were captured at the Twisp site and 143 were captured at the Methow site between 1 July 2015 and 30 June 2016. Utilizing the same mark/recapture efficiency trial data used for spring Chinook at each site (Tables 5-9), an estimated 3,172 ( $\pm 653,95 \%$ CI) and 15,421 ( $\pm 15,032,95 \%$ CI) wild 2014 brood Coho emigrated past the Twisp and Methow River traps, respectively.

Table 12. Mark/recapture efficiency trials used to estimate emigration of 2015 brood summer Chinook salmon (SBC) at the Methow River smolt trap in 2016.

## Juvenile Survival

## 2014 Brood Spring Chinook Salmon

Yearling emigrants accounted for $23.2 \%$ of all 2014 brood spring Chinook salmon migrating from the Twisp River, and $50.7 \%$ of the overall emigrants from the Methow River basin (Table 13). The 2014 brood had more emigrants per redd than average for both the Twisp and Methow rivers.

## Summer Steelhead

Since juvenile steelhead may emigrate as age-4 fish, completed emigration estimates have only been calculated for broods prior to 2013 (Table 14). The 2012 brood produced an estimated 45 and 44 emigrants from each redd in the Methow and Twisp river basins, respectively.

Table 13. Estimated emigrants-per-redd (EPR) and egg-to-emigrant survival for Methow Basin spring Chinook. Methow Basin and Twisp River estimates are for redds deposited upstream and downstream of the respective trap sites, and include redds that dewatered. Rows identified with a * include an estimate of over-winter emigration derived from a PIT tag array and added to the total number of emigrants estimated from smolt trapping activities. DNOT = Did not operate trap.

## Smolt to Adult Returns

The PTAGIS website (http://www.ptagis.org) was used to determine adult PIT tag detections at Columbia River adult fish ladder detection sites for wild Chinook (Table 15) and at Wells Dam for wild steelhead (Table 16). Unique adult detections were summed and divided by the number of juvenile salmonids tagged and released at the Methow and Twisp smolt traps by species to determine smolt to adult survival rates.

Table 15. Smolt to adult return (SAR) from release to Columbia River return by release year for PIT tagged wild yearling Chinook smolts encountered at the Twisp and Methow smolt traps.

## Discussion

River conditions at both the Methow and Twisp sites were generally favorable for trapping activities during the 2016 season. The Methow trap was not operated for 17 days between 21 April and 13 May because of high river discharge. The Twisp trap was not operated for 35 days between 10 April and 8 June, with 30 of those days spanning from 21 April through 20 May. Operating the traps during this time would make the traps susceptible to damage due to debris, potentially cause excessive fish mortality, and escalate safety concerns for employees working on the traps. Conversely, the Twisp trap did not experience the downtime due to low river discharge during the summer months like it has during many previous trapping seasons.

River turbidity was abnormally high for much of the spring trapping period due to the additional sediment input from recent wildfires in both the Methow and Twisp basins. This may have had an influence on the diel migration patterns of juvenile salmonids in the basin. In past seasons, trap captures and observations suggest that the majority of juvenile salmonid migration occurs during dark periods. The capture of the hatchery Chinook at the Methow trap was much lower than expected during the spring of 2016. A hypothesis for this occurrence is that a significant number of fish migrated past the trap during daylight hours (the trap was not operating during the day due to permit obligations). There was some data collected to support this hypothesis at the Twisp site, where the trap operates during all hours of the day. During a ten day period between 1 and 15 April, a significant number of fish were captured during daylight hours. These daytime captures accounted for over half of the wild spring Chinook and over one third of the total migrant steelhead captures during the same period. If fish were similarly passing the Methow trap during daylight hours, the spring portion of both the spring Chinook and steelhead estimates likely underestimate the actual number of emigrants.

River discharge was higher earlier in the season than usual, and we were forced to pull the traps from operation earlier than we have since the project started. This was problematic because many of the hatchery fish scheduled to be released upstream of the traps had not been released before the traps were pulled for high discharge. Since these hatchery fish are commonly used as surrogates for wild fish in mark/recapture trials, we were unable to conduct as many trap efficiency trials as desired at the higher river discharge levels experienced for much of the spring trapping period. With the mark/recapture trials that were conducted, the model discharge upper limit was extended for estimating yearling Chinook in the upper position at the Methow site. This should help reduce the variance in future estimate calculations. At the Twisp site, only two trials were performed in 2016 and more data points will be needed to produce a significant regression for high discharge periods. The trials that were conducted suggest that the efficiency of the traps stay fairly consistent once a certain discharge is reached.

Production estimates and associated variance estimates for the 2016 trapping season were made using the statistical methodology described in Murdoch et al. (2012). This methodology has minimal effect on the production estimate but corrects for the extremely high variances estimated by the former methodology. Once this methodology has been peer reviewed, all estimates from past years will be recalculated and reported.

Tissue samples (i.e., fin clips) were taken from subyearling Chinook captured at the Methow River trap in 2016 to determine the proportion of subyearling fish that were spring Chinook salmon. Spring Chinook salmon accounted for $97.0 \%$ of the Chinook sampled during the fall trapping period. Emigration estimates were produced for spring Chinook salmon during the fall trapping period at the Methow River trap site and the proportion of fish identified as summer Chinook salmon were removed. Emigration estimates are not produced for spring Chinook salmon that may emigrate before the fall period as subyearling fish. Therefore, spring Chinook production estimates for the Methow Basin, including Twisp River estimates, underestimate production by the portion of spring Chinook salmon emigrating as subyearling fish in the spring and summer, assuming that those fish do not move back upstream of the trap after initial capture.

Appendix B. Genetic assignments of migrant subyearling Chinook at the Methow River smolt trap.

# 2016 Methow Chinook salmon juvenile assignments 

Maureen P. Small and Cherril Bowman<br>Conservation Biology Unit, Molecular Genetics Lab, WDFW

Report, January 2017

## Summary

In fall 2016, emigrating natural-origin sub-yearling Chinook salmon were collected in the Methow River smolt trap. Because two genetically distinct types of Chinook salmon, a spring-run and summer-run, spawn in the Methow River, the juveniles could be from either or both run types, and the different run type juveniles may emigrate at different times. Further, the spring Chinook salmon population in the Twisp River, a tributary upstream of the smolt trap in the Methow River, is genetically distinct from Methow/Chewuch spring Chinook salmon population (Small et al. 2007) and some juveniles may have originated in the Twisp spring Chinook salmon population. We investigated the genetic identity of the juvenile Chinook salmon through comparisons to adult spring and summer Chinook salmon collections from the Methow River and an adult spring Chinook salmon from the Twisp River. We found that most of the juveniles were spring type and that about $25 \%$ of the spring type originated in the Twisp population.

## Methods

We genotyped 100 juvenile Chinook salmon (WDFW collection code 16FT, Table 1) at the 13 standardized GAPS loci as described in Small et al. $(2007,2009,2010)$ and compared them to Twisp River spring Chinook salmon, and Methow River spring and summer Chinook salmon genotyped at the same loci.

Juvenile identities were examined from two perspectives. The first analysis examined individual ancestry using a Bayesian analysis implemented in STRUCTURE (Pritchard et al. 2000). In this analysis, we hypothesized that there were two groups in the data set, spring and summer Chinook salmon, and estimated individual ancestry in two groups. Without knowledge of the origin or identity of individuals the program sorts the data set in order to achieve Hardy-Weinberg equilibrium and minimize linkage disequilibrium in each hypothesized group. To further identify juvenile origins, we used assignment tests implemented in GENECLASS (Piry et al. 2004) with the Rannala and Mountain algorithm (Rannala and Mountain 1997) to calculate the likelihood that the juvenile came from the Methow spring or summer Chinook salmon collection or the Twisp spring Chinook salmon collection based on the genotype of the individual and the allele frequencies of the baseline collections. The analysis was run with 50,000 burn-in runs and 200,000 iterations: the burn-in runs move the analysis away from starting conditions to prevent them from influencing the analysis.

## Results and discussion

One individual, 16FT0156, failed to produce a genotype and was excluded from analysis. The STRUCTURE analysis divided the adult spring and summer Chinook salmon into two distinct clusters
(Figure 1). Ninety three juveniles had $90 \%$ or greater ancestry in the spring Chinook salmon cluster and two juveniles had $90 \%$ or greater ancestry in the summer Chinook salmon cluster (Table 2). Note: we included only Methow River spring and summer collections in the STRUCTURE analysis to decrease the complexity of the analysis because genetic variance between Twisp and Methow spring Chinook salmon populations is below the resolving power of STRUCTURE.

Results from GENECLASS paralleled the STRUCTURE analyses and provided further resolution (Figure 2 and Table 3). We plotted the negative log likelihood assignment values for the juveniles and for the adult spring and summer Chinook salmon collections (Figure 2). The plot shows that the adult spring and summer Chinook salmon assigned well to their respective groups. The distinction indicated high power for distinguishing genetically between run groups. The plot also shows that three juveniles assigned to the summer collection (labeled in Figure 2). Nineteen juveniles assigned with less than $90 \%$ likelihood to a spring-run baseline collection. The second most likely assignment for each was the other spring-run collection indicating that the smolts were spring-run, and these were labeled "Spring" in Table 3. For instance, 16FT0014 assigned with $83 \%$ likelihood to Methow spring and with $17 \%$ likelihood to Twisp spring. It likely originated in the Methow spring-run population but had one or more alleles that were common in the Twisp spring-run population.

In summary, three smolts assigned with high likelihood to the Methow summer Chinook salmon collection and 96 smolts assigned to Methow or Twisp spring Chinook salmon collections.

## Acknowledgments

Juvenile samples were gathered by Charles Snow and David Grundy (WDFW). Funding was provided by Douglas Co. PUD and Washington State General Funds. Todd Kassler (WDFW) administered the contract.

Figure 1. Ancestry values for individual fish calculated in STRUCTURE. Each fish is represented by a bar of color with red corresponding to summer Chinook salmon ancestry and green corresponding to spring Chinook salmon ancestry. Individuals with "pure" ancestry have a single color in their bar and individuals with "mixed" ancestry have two colors in their bar. Individuals are in order of the collection code number so juveniles with spring ancestry can be compared with STRUCTURE ancestry values in Table 2 and GENECLASS assignments in Table 3.

Figure 2. Graph of negative log likelihood assignment scores from GENECLASS. Methow juveniles (blue diamonds) are abbreviated Juv. Highest likelihood values assigned 96 juveniles to spring and 3 to summer.

Table 1. List of samples used in the Methow Chinook salmon juvenile assignment tests.

| Code | Name | N |
| :---: | :---: | :---: |
| 16 FT | Methow juveniles -2016 | 100 |
| 05 HW | Methow spring | 42 |
| 05 HX | Twisp spring | 42 |
| $93 E C$ | GAPS Methow summer | 143 |

Table 2. Juvenile collection date, ancestry values and assignments from GENECLASS and STRUCTURE. See Figure 1 for graphic STRUCTURE data - percentage of ancestry in the two clusters (here summer and spring) is shown as percentage of colors in color bar in Figure 1. Samples labeled as "Spring" under GeneClass assignments assigned to one spring collection with less than $90 \%$ likelihood and the next most likely assignment was to the other spring collection.

Attachment B. In-stream PIT tagging of juvenile spring Chinook and steelhead in the Methow River basin in 2016.

# STATE OF WASHINGTON DEPARTMENT OF FISH AND WILDLIFE FISH PROGRAM-SCIENCE DIVISION <br> METHOW RESEARCH TEAM <br> 20268 HWY 20, Twisp, WA 98856 <br> Voice (509) 997-0048 FAX (509) 997-0072 

7 March 2017
To: Charlie Snow
From: Matt Young and Ben Goodman
Subject: 2016 in-stream PIT tagging in the Methow River basin.
Productivity of Methow River basin spring Chinook Salmon Oncorhynchus tshawytscha and summer steelhead O. mykiss is low due, at least in part, to the poor survival of natural-origin fish (Murdoch et al. 2012). However, it is unknown whether the diminished survival occurs at a particular life stage, or if survival is poor across all life stages. Murdoch et al. (2012) recommended that PIT-tag based assessment of survival could be useful in investigating limiting life stages for spring Chinook Salmon and summer steelhead. Instream PIT tagging of juvenile Chinook Salmon and steelhead parr has been conducted in the Methow Basin over the last several years to estimate parr-to-smolt survival, identify stream of origin for returning adults, evaluate life-history differences among specific stocks (e.g., emigration timing), or as part of an ongoing relative reproductive success study. In 2016, we conducted in-stream PIT tagging in the Twisp, Chewuch, and Methow basins with the objective of refining methodologies to estimate the population size of natural-origin juvenile spring Chinook Salmon and steelhead, while meeting sampling requirements of the relative reproductive success study of steelhead in the Twisp basin (i.e., 2,500 total parr assuming that 1,500 will be age- 1 parr). This memo summarizes the methods and results of our in-stream PIT tagging in 2016.

## Methods

We used a combination of angling and electrofishing to collect spring Chinook Salmon and steelhead parr in 2016. Angling was conducted following equipment rules for selective fisheries (i.e., unscented artificial flies or lures with a single, barbless hook) defined in annual sport fishing rule pamphlets for Washington State. Backpack electrofishing was conducted using a Halltech HT-2000 pulsed DC battery powered backpack electrofisher with a telescoping anode pole and stainless steel cable cathode. Boat electrofishing was conducted in a $13-\mathrm{ft}$ shocking raft using a Smith Root model 1.5 kVA electrofisher powered by a 2000-Watt generator with a bow-
mounted anode, and paired cathode skirts on each raft side. The raft allowed the rower to position the raft in the current while another person netted fish from a secure standing platform above the anode. Electrofisher voltage and frequency were altered by date and location to maximize capture efficiency and minimize fish injury. Sampling efficiency using these techniques varied throughout the sampling period in relation to river flows and staff availability. Start time, stop time, and the number of samplers (i.e., effort) were recorded for each angling event. Electrofishing effort was measured as the number of seconds the unit was operating (i.e., wand time). The number of crew members was also recorded for each electrofishing event.

In the Twisp River basin, angling and electrofishing were conducted at various locations in the Twisp River mainstem (mouth to rkm 46.9), Little Bridge Creek (mouth to rkm 7.8), and Buttermilk Creek (mouth to rkm 4.1). Angling effort occurred from 29 June to 7 September to target age- 1 and age- 2 steelhead parr. This time period was selected because water temperature and fish activity levels made them relatively susceptible to angling. Angling effort varied by location. The primary spawning reaches for summer steelhead sampled at the Twisp Weir were fished completely (i.e., a single angling pass was conducted along the entire length of each reach); this area consisted of the Twisp River mainstem from Upper Poorman Creek Bridge (rkm 7.8) to the middle of T7 (rkm 32.2), and the lower 2.4 km of Little Bridge Creek (LBC1). Outside of the primary spawning reaches, angling effort was reduced because the likelihood of capturing the progeny of adults sampled at the Twisp Weir declines in these areas. To reduce spatial bias in the sampling within these areas, 21 sites were randomly selected and each was subjected to 3 hrs of angling effort. These areas consisted of the remainder of the Twisp River mainstem from the Methow River confluence upstream to Roads End Campground (rkm 46.4), the upstream sections of Little Bridge Creek (bottom of LBC2 [rkm 2.4] to the top of LBC3 [rkm 7.8]), and Buttermilk Creek (mouth to top of BM2 [rkm 4.1]). Electrofishing in the Twisp River basin occurred after 20 September when most juvenile Chinook captured would be large enough for PIT tagging (i.e., $\geq 55 \mathrm{~mm}$ fork length) and prior to seasonal movements of fish out of the basin. Individual sampling sites for electrofishing in the Twisp River basin were selected by Douglas PUD staff using a Generalized Random Tessellation Stratified (GRTS) design. In the Twisp Basin, sampling effort was divided into three spatial strata; $20 \%(N=10)$ were downstream of the weir, $52 \%(N=26)$ were upstream of the weir, and $28 \%(N=14)$ were in tributaries.

The GRTS design allows random site selection while ensuring that the sampling design is spatially balanced. Sampling sites were selected from within the known redd distribution of spring Chinook Salmon and steelhead from previous years. Mainstem sites were 100 m long and tributary sites were 50 m long. Two types of electrofishing sampling methods were used at these sites; three-pass depletion sampling and single-pass sampling. In three-pass depletion samples, each electrofishing pass occurred in an upstream direction and all wetted area within the site that
could be accessed was sampled with approximately equal effort per pass. Single-pass sites were conducted in the same manner, but with only a single pass at each site.

To assess the feasibility of GRTS sampling on larger rivers, electrofishing also occurred in the Chewuch River basin and the Methow River mainstem. Electrofishing in the Chewuch River basin was conducted from 6 to 19 October. Within the Chewuch River mainstem, one electrofishing site was randomly selected within each of the 13 established stream sections from the mouth to the falls above Thirtymile Bridge (rkm 54.4). In addition, one electrofishing event occurred in each of the following Chewuch River tributaries: Boulder Creek, Eightmile Creek, Twentymile Creek, and Lake Creek. Tributary sites were randomly selected from within the first river kilometer of each tributary. Electrofishing in the Methow River mainstem was conducted from 5 to 28 October. Two shocking sites were selected within the Methow River mainstem that contained habitat suitable for rearing juvenile Chinook Salmon and steelhead parr within reach M4 (rkm 67.3-74.5). Both sites were sampled using a backpack electrofishing unit where safe wading was possible along the margins of the river. For deeper water inaccessible to backpack electrofishing, boat electrofishing was used. The rower of the raft allowed the current to carry the raft downstream while adjusting its orientation to facilitate netting of immobilized fish. Each site required multiple passes; each pass was as wide as the observed effective shocking range of the raft. After each pass, the raft was moved back upstream and the adjacent area was shocked until the entire area in the $100-\mathrm{m}$ long site had been covered completely. Each of the two sites was sampled completely on 5 October and a recapture pass was conducted on the upstream most site on 28 October. Electrofishing was also conducted in the Silver Side Channel, a perennial, spring-fed side channel of the Methow River, in support of an ongoing habitat restoration project. In order to assess fish assemblage and density, most of the channel was electrofished on two occasions; a spring pass (17 March) and a fall pass (20 October). Prior to the initiation of restoration work, electrofishing was also used to remove fish from the lower 0.7 rkm of the Silver Side Channel on 27-28 June.

Regardless of capture method, parr were held in 19-L plastic buckets filled with aerated river water until the sampling event was completed. Captured fish were anesthetized in a solution of tricaine methanesulfonate (i.e., MS-222) at a concentration of $40-60 \mathrm{mg} / \mathrm{L}$, scanned for presence of a PIT tag, measured for fork length to the nearest mm, and weighed to the nearest 0.1 g . All unmarked wild parr $\geq 55 \mathrm{~mm}$ were PIT tagged to prevent double sampling of individuals, and to estimate survival to other life-history stages (e.g., smolt to adult) or locations (e.g., in-stream PIT tag antenna arrays or Columbia River hydropower detection facilities). Parr with fork lengths from 55 to 64 mm were tagged with 9-mm PIT tags, while parr with fork lengths $\geq 65 \mathrm{~mm}$ were tagged with $12-\mathrm{mm}$ PIT tags. All hatchery origin fish captured during angling and electrofishing (i.e., fish that failed to emigrate) were euthanized to reduce the proportion of hatchery residuals in natal rearing areas. Sampling locations were geo-referenced using a hand-held GPS device. Fish were allowed to fully recover in a bucket of river water prior to release in a calm part of the
river near the sampling location. Tagging data was uploaded following standard protocols to the regional PIT tag database (PTAGIS) maintained by the Pacific States Marine Fisheries Commission.

## Results

In the Twisp River basin, we captured a total of 2,360 wild steelhead parr, 142 residual hatcheryorigin steelhead parr, and 576 wild Chinook Salmon parr during angling and electrofishing. Most wild Chinook Salmon and summer steelhead were tagged (Table 1) unless they were too small or other fish health concerns existed. Angling and electrofishing effort in 2016 was similar to the previous two years (i.e., since GRTS sampling was initiated); however, total catch of target species was lower than in these previous years (Table 2). Wild steelhead fork length in the Twisp Basin was greater for those captured by angling (mean = 148 mm ) than by electrofishing (mean $=94 \mathrm{~mm}$ ) in 2016 (Figure 1; $P<0.001$; Kolmogorov-Smirnov test).

In the Chewuch River basin, 638 steelhead parr and 180 Chinook Salmon parr were captured with 11.7 wand hrs of electrofishing effort, and most were PIT tagged (Table 3). In the Methow River basin, 175 steelhead and 604 Chinook Salmon parr were captured with 7.2 wand hrs of electrofishing effort and most were PIT tagged (Table 3). During the recapture pass in the upstream-most Methow River mainstem site, 25\% of the 20 target fish captured were recaptures from the original sample, despite three weeks between sampling events.

Date: 26 May 2016
Subject: Results of 2016 spring Chinook salmon spawning ground surveys and escapement estimates in the Methow River Basin.

Spring Chinook salmon are propagated at Methow Hatchery (MH) and used to supplement the natural spawning populations in the Methow River Basin. Hatchery origin adults (HORs) from supplementation programs are managed to have migration timing, spawn timing, and redd distribution similar to those of natural origin adults (NORs). Deviations from these life-history traits may have deleterious effects on the overall reproductive success of supplemented populations. The number of spawners, derived from estimates of redd abundance, provides critical information not only for survival and spawner-recruit analyses, but also for assessing freshwater smolt production. Knowledge of both the productivity of the population (i.e., recruits per spawner), as related to the total abundance of spawners, and the proportion of HOR fish on the spawning grounds should provide valuable insight regarding the factors limiting the number of NOR adults. In addition to spawner abundance, the proportion of stray HOR fish on the spawning grounds may also assist in understanding the productivity of the population (i.e., stray fish may be maladapted to the Methow Basin). Spring Chinook salmon spawning ground surveys and associated activities (i.e., broodstock collection and management) were used to evaluate spawn timing, distribution, and tributary-specific escapement levels within the Methow River basin.

## Methods

## Run Escapement

Adult spring Chinook salmon were trapped and sampled at Wells Dam to assess migration timing, origin composition, and to collect broodstock for MH (Tonseth 2016). All trapped fish were sampled for marks (fin-clips) and tags (CWT). Scale samples, sex, and fork length data
were collected from all potential NOR fish, and NOR fish retained for broodstock were also tissue sampled for DNA analysis to determine genetic origin (i.e., Methow basin origin and Twisp or non-Twisp). All HOR fish were sampled for scales, sex, and length, and passive integrated transponder (PIT) tags were inserted in the pelvic girdle of all released fish (HOR and NOR) to assess sex ratio of the 2016 brood. All ad-clipped adults were assumed to be returns from Winthrop NFH production. Ad-clipped jacks were assigned to either Winthrop NFH production, or CCT production (Okanogan Basin and Chief Joseph Hatchery) according to proportional returns of PIT-tagged fish. Gender was determined using ultrasound. All trapped fish were either held pending DNA and scale analyses and subsequently transported to MH as broodstock or placed back in the fish ladders upstream of the traps.

Digital video records of fish passage at Wells Dam between 22 May and 2 July for both ladders were reviewed to exclude summer Chinook salmon from the spring Chinook salmon count and vice versa. The number of fish that were double counted (i.e., re-ascensions) or fell back (i.e., fell below without re-ascending) were estimated based on PIT-tag detections at in-stream interrogation sites and mainstem Columbia and Snake River dams. No estimates of predation, pre-spawn mortality or illegal removal (i.e., poaching) were made.

## Spawning Ground Surveys

Spring Chinook salmon redds were individually georeferenced with hand-held global positioning system (GPS) devices for subsequent mapping and analyses and all pertinent data were collected for each redd. Most reaches were surveyed every six to eight days during the spawning season (August and September). Female carcass locations (river kilometers [rkm]) were used as surrogates for spatial redd distribution of hatchery and natural origin spawning.

## Spawner Composition, Demographics, and Egg Deposition

Spawning population characteristics were derived from biological data collected from carcasses recovered during surveys. Location, origin, sex, fork length, post-orbital-to-hypural-plate (POH) length, egg retention (females), and scale samples were collected from each carcass when possible. Tissue samples were collected from NOR fish, and a small number of HOR fish for genetic analyses; most DNA samples from HOR fish were collected at Methow Hatchery during spawning activities. Carcass locations were recorded using hand-held GPS devices and all carcasses were sampled for CWTs using hand-held electronic detection wands. Spring Chinook salmon released from Methow Hatchery are tagged with a CWT but no external mark (to avoid removal in mark-selective fisheries), thus requiring the use of electronic detectors. Most other HOR fish released in the Upper Columbia are externally marked with an adipose fin-clip in addition to the CWT to designate hatchery origin. Snouts were sent to the WDFW CWT Lab for tag extraction and decoding. Scales were sent to the WDFW Ageing Lab for age determination.

Fish age was determined either through CWT or scale analysis. Scale analysis was also used to confirm origin for fish with no detectable hatchery mark or tag (i.e., NOR).

Egg retention was determined for female carcasses with an intact abdomen by counting the number of eggs present. The percentage of eggs retained was determined by dividing the number of eggs counted by the mean fecundity for the fish's specific age and origin derived from 2016 MH broodstock (WDFW, unpublished data). Female carcasses with intact abdominal cavities, a large number of eggs, and no external signs of spawning (i.e., eroded caudal fin) were categorized as pre-spawn mortalities. Estimated egg deposition was calculated using mean fecundities from MH broodstock (i.e., MetComp stock for Methow and Chewuch subbasins, Twisp stock for Twisp subbasin) and adjusted for mean egg-retention rates.

## Natural Replacement Rate

The natural replacement rate (NRR) for each brood was calculated by adding the number of recruits ( r ) from successive return years that originated from the same brood year (i), and dividing the sum by the number of spawners (S) for that brood year calculated from expanded spawning ground surveys, as follows:

$$
\text { NRR }=\left(r_{i+1}+r_{i+2}+r_{i+3}+\ldots\right) / S
$$

Estimated spawning escapement was derived from redd counts expanded by fish-per-redd values. Prior to 2006, fish-per-redd values were calculated from Wells Dam counts and adjusted for the proportion of jacks (age-3 fish) in the run (Meekin 1967). Since 2006, fish-per-redd values have been calculated using the male-to-female sex ratio from run-at-large sampling at Wells Dam. In 2016, fish-per-redd values were calculated on the population remaining after broodstock collection and removal of surplus hatchery-origin fish. Recruits were expanded to account for non-selective fishery harvest and indirect mortality attributed to selective fisheries.

## Stray Rates

The composition of HOR fish on spawning grounds, and associated stray rates were determined by expanding all CWT recoveries by the code-specific tag-retention rates and stream-specific sampling rates from spawning ground surveys. HOR fish were considered strays depending on their release and recovery locations. All MH fish recovered in a stream within the Methow River watershed from which they were not released were considered within-basin strays. Out-of-basin strays included all fish recovered in streams other than their stream of release. When fish are retained for broodstock, it is unknown whether they would have eventually migrated to their natal (or release) streams or to "non-target" areas. Therefore, fish retained for broodstock were excluded from stray rates calculations. Further, all CWT recoveries of the 1992 and 1994 broods were within broodstock collections, thus stray rates were not calculated for these broods, and no

Twisp or Chewuch fish were released from the 1995 brood year. The Methow and Chewuch programs were maintained and released as an aggregate stock (Methow Composite) in the 1998 and 2000 brood years; stray rates could not be determined for the individual release sites.

## Results

## Migration Timing and Run Composition

The 2016 spring Chinook salmon migration to Wells Dam was monitored between 3 May and 24 June. Overall, wild fish migrated to Wells Dam two days earlier than hatchery fish (Table 1). Based on PIT tag detections at Wells Dam fish ladders, an estimated two fish were double counted and 97 fish fell below Wells Dam after being counted and did not re-ascend; excluding these totals, the estimated spring Chinook salmon to Wells Dam (including broodstock) was 5,211 fish. The run was composed primarily of hatchery fish ( $87.3 \%$ ), $76 \%$ of which were adipose fin-clipped. After correcting for sex determination errors and accounting for fish retained for broodstock $(N=559)$, fish destined for the Okanogan Basin $(N=372)$, and fish removed as surplus $(N=3,080)$ the remaining estimated escapement in the Methow River was 1,200 fish.

## Redd Distribution, Spawn Timing, and Spawner Demographics

Spawning ground surveys were performed on foot between 1 August and 29 September. A total of 361 spring Chinook redds were constructed in the Methow basin in 2016 (Tables 2-4); the majority of redds were found in the Methow River subbasin ( $64.0 \%$; $N=231$; Table 2). The greatest number of redds within that subbasin were found in the 9 km reach downstream of Weeman Bridge ( $N=75$ ). On average, Methow Hatchery females and wild females spawned at the same time in both the Methow and Twisp subbasins, but in the Chewuch subbasin, Methow Hatchery females spawned four days earlier than wild females (Tables 5-7). On average, wild females spawned between six and 15 km further upstream than Methow Hatchery females, depending on subbasin (Tables 5-7).

Based on expanded redd counts, there were an estimated 697 spawners in the Methow River basin in 2016, of which 320 (45.9\%) were estimated to be wild (NOR) fish (see Tables 2-4). Estimated spawning escapement does not include hatchery or wild fish collected for broodstock. Wild fish comprised $67.4 \%, 62.3 \%$, and $35.7 \%$ of the estimated spawning escapement in the Twisp, Chewuch, and Methow subbasins, respectively (see Tables 2-4).

A total of 169 Methow Hatchery and wild fish carcasses were recovered for which age, origin, gender, and length were measurable (Table 8). Comparisons of hatchery and wild fish show similar mean lengths within age groups for both MetComp and Twisp stocks (Table 8).

Egg retention was estimated for 133 of the 174 female carcasses examined. Using mean fecundities from MH broodstock (MetComp and Twisp), adjusting for mean egg-retention rates, and accounting for the proportion of hatchery and wild females by age class on the spawning grounds, an estimated total of 1,426,641 eggs were deposited in the Methow River basin in 2016 (Table 9).

| 2016 | 13 | 4,551 | 0.04 | 46 | 209,262 |

## Natural Replacement Rates

Natural replacement rates (NRR) for the latest complete brood (2010) were less than 1.0 in all subbasins (Chewuch $=0.43$; Methow $=0.20 ;$ Twisp $=0.57$; Appendices A-C). Though all NRR values were below replacement, 2010 rates were two to three times greater than those in 2009. HRR values from the 2010 brood were between nine and 32 times greater than corresponding NRR values within subbasins (Appendices A-C).

## Stray Rates by Brood Year

Based on total expanded CWT recoveries, an estimated $37.1 \%$ of the 2010 brood Chewuch spring Chinook salmon was recovered on spawning grounds of other recipient spawning areas (Appendix D). Excluding broods with no usable spawning ground recovery information (1992, 1994-1995, 1998, 2000), the recovery rate of Chewuch River fish in stray areas (mean = 32.7\%) was greater than the $5 \%$ target. Based on total expanded CWT recoveries, an estimated $8.6 \%$ of the 2010 brood Methow spring Chinook salmon was recovered on spawning grounds of other recipient spawning areas (Appendix E). Excluding broods with no usable spawning ground recovery information (1992, 1994, 1998, 2000), the recovery rate of Methow River fish in stray areas (mean $=3.5 \%$ ) was less than the $5 \%$ target. Based on total expanded CWT recoveries, an estimated $24.3 \%$ of the 2010 brood Twisp spring Chinook salmon carcasses were recovered on spawning grounds of non-target areas (Appendix F). Excluding broods with no spawning ground recoveries (1992, 1994-1995), the recovery rate of Twisp River fish in stray areas (mean = $22.6 \%$ ) was greater than the $5 \%$ target.

## Stray Rates within the Methow Basin

A total of 104 coded wire tags (CWTs) were successfully decoded from the adult spring Chinook salmon collected during spawning ground surveys in the Methow River basin in 2016. These fish were expanded by tag-specific retention rates and stream-specific sample rates to account for 334 fish (Appendix G). As a percent of the spawning escapement, most within-basin strays were recovered in the Chewuch subbasin (Table 10-12; 8.6\% Methow and Twisp releases combined). Out-of-basin stray fish were found in the Chewuch and Methow subbasins (Table 10 and 11; Appendix G).

## Stray Rates outside the Methow Basin

A total of 77 fish from Methow Hatchery were estimated to have strayed to recipient populations outside the Methow River basin from all broods examined (Table 13). Of these, 58 fish strayed into other spring Chinook salmon populations (e.g., Chiwawa and Entiat Rivers; Table 13). Stray Methow Hatchery fish have comprised less than 5.0\% of the overall estimated spawning escapement to the Entiat River (Table 13) and did not exceed 5\% in any other population.

Table 10. Spawning escapement (\%) of hatchery release groups in the Chewuch subbasin. Percent of spawning escapement comprised by wild fish is not included.

| Run year | Estimated spawning |  |  | Hatchery stock (\% of spawning escapement) |  |  |  |  |  |

${ }^{\text {a }}$ Fish was recovered during WDFW genetic study trapping and was not included in spawning escapement estimate.
${ }^{\mathrm{b}}$ Recovery was an age-1 juvenile non-migrant and not included in the estimated spawning escapement.

## Discussion

2016 marked the first year since 2003 that four-year old hatchery fish would not be returning to a location they were released from in the Methow Basin. Hatchery fish were not planted in the Chewuch River in 2014 from the 2012 brood, and in 2016 there were no four-year old Chewuch hatchery origin returns. Additionally, Chewuch River releases decreased to below 100,000 fish starting with the 2010 brood, and are currently set at about 60,516 fish annually. The lower release numbers in general, and the absence of hatchery returns from the 2012 brood specifically, reduced pHOS in the Chewuch River in 2016. Although pHOS in 2016 was lower than the 2003-2015 mean pHOS values in each subbasin (Methow, Twisp, and Chewuch) the Chewuch subbasin had the greatest reduction overall. The 2016 pHOS value of 0.38 was the first time the Chewuch subbasin had a pHOS value under 0.50 in the WDFW survey era (2003-present).

Hatchery releases resumed in the Chewuch subbasin with the 2013 brood, released in 2015, and four-year old hatchery fish will be returning in 2017. Proposed projects in the Chewuch subbasin include planting additional hatchery-origin adults in the Chewuch prior to spawning to increase spawner abundance. Low sampling rates of natural-origin fish at Wells Dam, PIT array efficiencies, and the absence of an instream weir are some of factors that increase the uncertainty surrounding how many natural-origin and hatchery-origin spawners are destined for the

Chewuch in any given year, and therefore how many extra fish should be planted. Managers should evaluate the benefits and consequences of increasing pHOS closely to determine how these actions might affect the population of natural-origin spring Chinook in the Chewuch subbasin and the Methow River Basin as a whole.

Appendix D. Chewuch River spring Chinook expanded CWT recoveries. Both Methow and WNFH Hatchery are considered target broodstock locations for Chewuch releases. Stray rate is the percent of spawning ground recoveries collected on non-target spawning grounds. $\mathrm{T}=$ target, NT = non-target, W = Wells Dam, Com. = commercial, Sp. = sport, Trbl. = tribal. 1998 and 2000 MetComp broods share one CWT for both release rivers and are not included.

## Subject: Results of 2016 brood steelhead spawning ground surveys and escapement estimates in the Methow River Basin.

Summer steelhead are propagated at Wells Hatchery and used to supplement the natural spawning populations in the Methow and Okanogan rivers. Hatchery origin adults (HORs) from conservation programs should have migration timing, spawn timing, and redd distribution similar to those of natural origin adults (NORs). Deviations from these life-history traits may have deleterious effects on the overall reproductive success of supplemented populations. The number of spawners, derived from a combination of redd counts, surveyor efficiency modeling, and PIT tag array expansions, provides critical information not only for survival and spawnerrecruit analyses, but also for assessing freshwater smolt production. Knowledge of both the productivity of the population (i.e., recruits per spawner), as related to the total abundance of spawners, and the proportion of HOR fish on the spawning grounds should provide valuable insight on the factors limiting the number of NOR adults. In addition to spawner abundance, the proportion of stray HOR fish on the spawning grounds may also assist in understanding the productivity of the population (i.e., stray fish may be maladapted to the Methow Basin). Steelhead spawning ground surveys, hatchery broodstock trapping, creel surveys, and PIT tag arrays were used to evaluate spawn timing, distribution, and tributary-specific escapement levels within the Methow River basin. While steelhead from Wells Hatchery were released in both the Methow and Okanogan populations, this report focuses on the Methow population. Monitoring and evaluation activities are conducted in the Okanogan Basin by the Colville Confederated Tribes (CCT) and those activities are reported separately (Miller et al. 2017) unless specifically relevant to Methow Basin activities.

## Methods

## Run Composition

Broodstock were collected at Wells Dam from a composite of both the Methow and Okanogan populations. Adult fish were trapped a maximum of three days per week and were retained for broodstock as necessary to achieve collection goals for HOR and NOR fish (Tonseth 2016). All trapped steelhead were sampled for hatchery marks, and scale samples were collected from all fish to determine age and origin (i.e., HOR or NOR). In 2016, trapping was conducted on both Wells Dam fish ladders.

PIT tag records were reviewed to determine if fish migrated through fish ladders more than once; these events cause overestimation of the total count at Wells Dam. Dam fallback and double counting of fish at Wells Dam were estimated using data from PIT tag detections at Columbia River hydroelectric facilities or within tributaries. The total number of double counted HOR and NOR fish was expanded to the run-at-large HOR and NOR totals. Fish that were detected at dams or within tributaries downstream of Wells Dam after their last detection at Wells Dam, before or during the presumed spawning period were considered fallbacks; fish were not considered fallbacks if downstream detection (e.g., Rocky Reach juvenile bypass [RRJ]) was consistent with likely kelt migration timing. Total fallback was calculated by expanding the estimated fallback proportion of HOR and NOR fish to the run-at-large HOR and NOR totals at Wells Dam.

Steelhead passing Wells Dam were subjected to local selective fisheries, and creel surveys were used to estimate the number of steelhead removed from the Methow, Columbia, Okanogan, and Similkameen river basins (Maitland et al. 2016). Estimates of tribal fisheries conducted by the CCT at Chief Joseph Dam, the mouth of the Okanogan River, and in the Okanogan Basin were provided by CCT staff (Mike Rayton, personal communication). Run escapement estimates were calculated for the Methow and Okanogan rivers by applying the proportion of fish that migrated to each basin based on results of local radio-telemetry studies (English et al. 2001, 2003) to the estimated number of HOR and NOR steelhead passing Wells Dam. Basin-specific fishery removal and indirect mortality (5\%) estimates, along with local broodstock collections were subtracted from the estimated escapement to each basin to determine the number of steelhead available for natural spawning. No estimates were made of pre-spawn mortality or illegal removal (i.e., poaching).

## Spawn Timing and Redd Distribution

An evaluation of spawn timing and redd distribution in the natural environment was conducted in the Twisp River (Goodman et al. 2017). Adult steelhead on their upstream spawning migration were trapped at the Twisp weir and sampled for hatchery marks, sex, and origin. All NOR fish were sampled, tagged and released upstream from the weir except for fish retained for
broodstock. HOR fish were also sampled, tagged, and released upstream of the weir consistent with escapement goals and objectives of an on-going steelhead relative reproductive success study (RRS) in the Twisp River. These objectives targeted a spawning population upstream of the Twisp River weir comprised of equal populations of NOR and HOR fish. All excess HOR steelhead were lethally removed from the spawning population. All steelhead released upstream of the weir received uniquely colored anchor tags that represented their origin and sex (green $=$ NOR male, pink = HOR male, blue = HOR female, red = NOR female). The assignment of colored anchor tags rotates each year to avoid any spawning success bias that could be associated with the presence of anchor tags. Visual observation of these tags was used to assess the spawn timing and location of HOR and NOR fish. Observations of anchor tagged fish on redds were used for spawn timing analyses and to determine redd distribution.

Historically, the Methow River basin was divided into four geographic subbasins; the upper Methow, lower Methow, Chewuch, and Twisp, and index areas of annual spawning activity were established within each subbasin and index areas were surveyed weekly. In 2016, a combination of methods was implemented to estimate spawning escapement and total redds. In the Twisp subbasin, comprehensive surveys served as the primary methodology to estimate total redds (Goodman et al. 2017). Escapement estimates in Methow River subbasins and lower Methow River tributaries were estimated via PIT tag detections at lower Methow River and subbasin antenna arrays (WDFW, unpublished data); redd totals were back-calculated using the run-atlarge fish-per-redd value. Redd surveys were performed weekly in lower Methow River index reaches as conditions permitted; one-time redd surveys were performed around peak spawning in non-index reaches. The application of the surveyor efficiency model previously developed was not applied to redd counts in 2016 therefore redd totals in lower Methow River reaches should be considered minimum values. Both hatchery outfall channels were surveyed weekly. Winthrop NFH outfall survey data was provided by USFWS. Steelhead redds were individually flagged with date, redd number, and location recorded on each flag. Each redd was also recorded with hand-held global positioning system (GPS) devices for subsequent mapping.

## Natural Replacement Rate (NRR) and Stray Rates

To estimate run escapement (parent broods) to the Methow Basin, steelhead returning to Wells Dam were apportioned to the Methow Basin based on radio-telemetry data (English et al. 2001, 2003). The NRR for each brood was calculated by adding the number of recruits ( $r$ ) to Wells Dam, based on total age determined from scales, from successive return years (i) that originated from the same parent brood. The total number of recruits was divided by the number of spawners ( $S$ ) for that brood year:

$$
\mathrm{NRR}=\left(r_{i+1}+r_{i+2}+r_{i+3}+\ldots\right) / S
$$

Estimated run escapement of parent broods ( $S$ ) are apportioned to the Methow and Okanogan basins based on radio telemetry data applied to run-at-large sampling totals at Wells Dam. Fish
collected for broodstock and incidental mortality as a result of the local fishery were excluded from escapement totals. Recently, PIT tags have provided the ability to estimate fallback and the total number of double counted fish at Wells Dam fish ladders.

Recently, PIT tag antenna arrays have also been deployed at or near the mouth of many spawning tributaries on the upper Columbia River. This technology allows the escapement of Wells Hatchery steelhead to tributaries downstream of Wells Dam to be estimated. Stray rates to the Wenatchee and Entiat populations can be estimated using PIT tag rates from run-at-large sampling at Priest Rapids Dam. Since all returning Wells Hatchery steelhead were from a single stock (MEOK), evaluating within-basin straying is not relevant from a genetic risk perspective. Homing fidelity was assessed via PIT tags that were inserted into a portion of the 2012 and 2013 brood fish and the release location of tagged fish was recorded during release monitoring.

None of the 2012 or 2013 brood releases from the Wenatchee Basin were given unique external marks to distinguish them from Wells Hatchery, Methow Hatchery, or WNFH releases. Only fish released from Ringold Hatchery were identified as strays. The number of stray HOR steelhead reported should be considered a minimum value. Unmarked HOR fish (identified through scale analysis) were apportioned to local or stray populations based on proportions of externally-marked fish in the weekly collections. Since stray HOR fish are largely no longer distinguishable from local HOR fish, all comparisons of HOR and NOR fish include all hatchery-origin fish.

## Results

## Run Composition

Stock assessment and collection of the 2016 brood Wells Hatchery steelhead broodstock occurred at Wells Dam between 3 August and 27 October 2015. During that time, a total of 8,358 steelhead passed Wells Dam. Of those fish, 442 (5.3\%) were sampled to determine origin through hatchery marks and scale samples. Of the sampled fish, 211 HOR steelhead were retained for broodstock purposes. All remaining steelhead were released into the west or east ladders upstream of the traps.

After removing the Wells Hatchery broodstock, the number of fish estimated to have been double-counted at Wells Dam, and the number of fish estimated to have fallen back below Wells Dam that did not re-ascend, the net run escapement upstream of Wells Dam for the 2016 brood was 8,422 fish (Table 1). Analysis of scale samples and observations of hatchery marks indicate that NOR fish comprised $22.7 \%$ of the steelhead run to Wells Dam (77.3\% HOR). Based on biological sampling of steelhead during broodstock collection, identification of hatchery marks, and coded-wire tags from fish retained for broodstock, only $3.3 \%$ of total escapement was
composed of out-of-basin stray hatchery fish from the Wenatchee Basin, Ringold Hatchery, and Idaho. The abundance and relative proportion of NOR steelhead in the 2016 brood return was great enough to allow a selective sport fishery in the Methow, Okanogan, and Similkameen rivers, as well as the mainstem Columbia River. Creel censuses conducted during these fisheries estimated 1,384 adipose fin-clipped steelhead were retained (total HOR fish mortality = 1,404; Table 2; Maitland et al. 2016, with unpublished corrections). Indirect mortality of steelhead captured and released during the fisheries was assumed to be $5 \%$ and resulted in estimated mortality of 37 NOR steelhead (Table 2). Remaining steelhead were assigned to the Okanogan and Methow Basins based on results of radio-telemetry studies (see Table 1; English et al. 2001, 2003). An estimated 323 and 1,046 wild fish were available for natural spawning in the Okanogan and Methow River basins, respectively (see Table 1). Historic steelhead passage, mortality, and escapement data are presented in Appendix A.

Based on radio-telemetry data (English et al. 2001, 2003), an estimated 58.0\% of the hatchery fish passing Wells Dam were destined for the Methow Basin. After broodstock and fishery removal, an estimated 2,468 HOR and 1,046 NOR steelhead were available for natural spawning in the Methow River basin (see Table 1), resulting in a basin pHOS estimate of 0.70 prior to spawning.

Table 1. Escapement and disposition of the 2016 brood summer steelhead passing Wells Dam. HOR $(N=211)$ fish removed for broodstock at Wells Dam are not included in the escapement estimate above Wells Dam. Methow and Okanogan River escapements are based on radiotelemetry data (English et al. 2001, 2003), which account for $90.4 \%$ and $91.6 \%$ of the hatchery and wild escapement, respectively. Dam count includes passage from 15 June 2015 through 14 June 2016.

## Twisp River Migration Timing, Spawn Timing, and Redd / Spawner Distribution

PIT-tagged steelhead were detected between 27 February and 4 June as they ascended the Twisp River to spawn. Based on recaptures of PIT-tagged fish above the Twisp River array, detection efficiency for adult steelhead was $97.5 \%$. Thirteen NOR steelhead were retained for broodstock. A total of 23 HOR steelhead were removed as surplus at the weir and 48 HOR steelhead were retained for broodstock. Few observations were made of anchor-tagged steelhead in 2016, so comparisons of spawn timing and spawner distributions of hatchery and wild fish were not made.

Redd surveys in the Twisp River basin were conducted from 10 March to 3 June. Redd surveys in the mainstem Methow River from the MRW array upstream of Winthrop downstream to Pateros were conducted from 4 March to 2 June. Early, prolonged high flow precluded surveyors ability to effectively document steelhead redds in 2016, so all subbasin redd totals should be considered minimum values. Based on PIT-based escapement estimates (Truscott et al. 2017), removal of fishery harvest, and comprehensive Twisp River redd counts (Goodman et al. 2017), an estimated 682 steelhead redds were created in the Methow River basin in 2016 (Tables 3-5). Historic redd counts for each of the subbasins are listed in Appendices B1-B4.

Based on biological sampling during 2016 run evaluation at Wells Dam, the age distribution of HOR steelhead was skewed towards 1-salt fish (72.6\%); NOR steelhead were also skewed towards 1-salt fish (61.4\%). Based on scale analysis, $29.6 \%(N=42)$ of the steelhead sampled at the Twisp River weir were NOR (Table 6). Using expanded redd counts by tributary, and the mean fecundity from Wells Hatchery broodstock by salt age and origin, an estimated 3,504,116 were deposited in the Methow Basin (Table 7). This estimate may be biased towards hatchery (ad-clipped) fish and not representative of actual spawners since the majority of fish used to estimate mean fecundity were from Wells Hatchery broodstock.

Table 7. Estimated 2016 steelhead redd totals from PIT-based expansions and surveyor efficiency model and estimated egg deposition in the Methow Basin. Fecundities are from Wells MEOK HOR females and Twisp/Omak NOR females and proportions are estimated from PITbased escapement (mean; \%): HOR 1-salt (4,615; 35.7), HOR 2-salt (6,063; 13.5), NOR 1-salt (4,982; 31.2), NOR 2-salt (5,941; 19.6). Twisp redd total is from Table 5.

| Area | Redds | \% of | Estimated egg deposition |  |  |  |  |  |  |

## Natural Replacement Rate (NRR)

A total of 442 steelhead were trapped and sampled at Wells Dam, of which 86 were determined to be NOR. The number of NOR fish observed during trapping was expanded to run-at-large weekly ladder counts to estimate the total number of NOR fish returning to Wells Dam after excluding fish that ascended the fish ladders multiple times ( $N=2,094$ ). Expanded return at age was based on scale analysis of NOR fish sampled during trapping, resulting in an estimated total of 1,483 NOR steelhead returning to the Methow Basin prior to broodstock collection, estimated fallback, and Columbia River fishery-related mortality (Table 8). The Methow estimate is a subtotal of total Wells returns and is apportioned based on radio-telemetry estimates (English et al. 2001, 2003). The NRR of the Methow Basin steelhead population was below replacement (i.e., < 1.0) in each of the fourteen brood years examined (Table 9). A plot of NRR verses run escapement suggests that high spawner escapement reduces overall productivity rates in the Methow Basin (Figure 1).

Table 8. NOR steelhead sampling at Wells Hatchery and expanded age composition by brood year of Methow Basin recruits ( $70.8 \%$ of NOR returns to Wells Dam). Brood year totals exclude the estimated number of double counted fish from 2009 through 2016.

Wild Steelhead at Wells Dam

Figure 1. Methow Basin steelhead run escapement (HOR + NOR; x-axis) verses natural replacement rate (NRR; y-axis) for parent brood years 1996-2010.

## Straying rates of Wells Hatchery Steelhead

Detections at PIT tag arrays were used to evaluate overall spawning escapement above the PIT tag array site and to estimate the contribution of Wells Hatchery steelhead releases to tributaryspecific spawning escapement estimates. Based on completed adult return data from the 2012 brood, stray rates for Methow Basin steelhead releases averaged 9.6\% across two release locations (Table 10). Though 2013 brood adult returns are incomplete, stray rates ranged from 3.3 to $11.8 \%$ for Methow Basin and Columbia releases (Table 10). One fish from the 2013 brood Columbia River release was detected in the Entiat Basin during the spring spawning period. Extrapolating the potential number of returns to the Entiat River is not feasible with one detection. Expansions with so few detections have exceedingly high uncertainty.

Table 10. Detection of adult HOR summer steelhead released from Wells Hatchery into Methow Basin tributaries. Detections of 2013 brood releases are considered incomplete because they include only 1-salt returns. Detections in the Lower Methow / Wells pool are not considered strays for any of the release groups. HOR steelhead were not released in the Chewuch River after the 2010 brood. All areas other than Wells Pool and tailrace are considered non-target locations for Columbia River (Wells Hatchery) releases.

| Brood | Release <br> river <br> (donor pop.) | Recipient river, river area, or tributary |  |  |  |  |  |  |  | $\begin{gathered} \text { \% } \\ \text { stray } \end{gathered}$ |

## Discussion

2016 marked the second consecutive spring following major wildfires in the Methow Valley. A large portion of several tributary subbasins were burned. As a result, nearly every tributary, large or small contributed sediment to the Methow River during spring freshets. Coupled with early runoff, increased sediment and turbidity precluded effective spawner and redd surveys for nearly all of the survey period from March through May. Increased sediment transport and alterations to the timing and intensity of runoff in wildfire-burned areas may affect the timing, distribution, and success of steelhead spawning in the Methow Basin for years to come. The reliability and persistence of PIT tag arrays in the Methow Basin and the data collected through them is now critically valuable.

Historically, the population of steelhead escaping to the Methow Basin has been largely comprised of hatchery-origin fish (80-90\%). Recreational fisheries can substantially reduce pHOS , but are often concluded because of take limits on incidental mortality of natural origin fish by anglers, not because few hatchery origin fish remain to be captured. In recent years, however, spawn escapement estimates derived through PIT tag detections throughout the Methow Basin indicate that pHOS goals are likely being achieved in some, often smaller, tributaries, particularly those without releases of juvenile hatchery steelhead. Between 2011 and 2015, mean pHOS was less than 0.50 in Gold Creek, Libby Creek, Beaver Creek, and the Chewuch River. During the same time period, mean pHOS in the Twisp River and Upper Methow River was 0.62 and 0.65 , respectively. With the exception of Beaver Creek, pHOS was less than 0.50 in every major spawning tributary in the Methow Basin in 2016. The one area in the Methow Basin that consistently has more hatchery-origin fish in the spawning population is the Methow mainstem between Winthrop and Pateros. In the last three years, pHOS has ranged from 0.71 to 0.87 . With the future possibility of hatchery-origin fish being released in the lower river, an effective and ongoing recreational fishery will be essential to achieving pHOS goals in all spawning areas of the Methow Basin.

Appendix C. Summer steelhead run escapement, broodstock collection, fishery-related mortality, and maximum spawning escapement estimates at and above Wells Dam. Methow and Okanogan River escapements are based on radio-telemetry data (English et al. 2001, 2003), which account for $90.4 \%$ and $91.6 \%$ of the hatchery and wild escapement upstream of Wells Dam, respectively. Total count at Wells Dam includes passage from 15 June (run year) to 14 June (spawn year) for brood years 2003 to present; total Wells Dam count for previous years includes the total reported for the run year (prior to spawn). Ladder counts are based on DCPUD raw data for brood years 2000-2011; data for brood years 1999 and 2012 was based on data from FPC.org. For brood years 2007-2015, proportion of hatchery and wild fish at Wells Dam was estimated through run-at-large sampling; in previous years, proportions were calculated from broodstock trapping records. Estimated double counts and fallback were based on expanded PIT tag interrogation data. Estimated fishery mortality in the Columbia River for brood years 2003-2005 includes fishery-related mortality in the Wells Dam tailrace; all other fishery mortality in the Columbia River occurred in the section between Wells Dam and Chief Joseph Dam. Estimated fishery mortality for hatchery fish in the Methow Basin includes hatchery fish removed as excess. For brood years 2001 and 2002, WDFW fishery mortality (Columbia) was estimated from catch record cards. CCT fishery data were provided by Mike Rayton (unpublished data).

| Brood year | Total count at Wells Dam based on trapping |  | Wells Hatchery broodstock retained |  | Estimated double counts at Wells Dam |  | Estimated fallback below Wells Dam |  | Estimated WDFW fishery mortality |  | Estimated CCT fishery mortality |  | Estimated run escapement (using radio-telemetry data) |  |  |  | Estimated fishery mortality |  |  |  | Local broodstock retained |  |  |  | Estimated maximum spawning escapement (using radiotelemetry data) |  |  |  |
